THURSDAY, MAY 4, 1876

THE PROGRESS OF THE LOAN COLLECTION[1]

THE investigation of the nature of those forces by which the material world is ceaselessly being moved and transformed, enlists in our day the energies of a host of scientific workers. It would be hard, perhaps, to mention a department of natural science for the study of which a good knowledge of the fundamental principles of what we now term physics is not at least a valuable and indispensable qualification, if not indispensably required. To the geologist and the biologist, no less than to the astronomer and the chemist, will such knowledge be imperative. Considering the widespread ramification of this division of science, it is not wonderful that the apparatus belonging to it should occupy so large a share of the available space in the present collection.

The remark formerly made, that much of the interest awakened in this loan collection will centre in its historical element—in the primitive forms of apparatus that represent, in some sort, the germs of some great development of scientific thought—holds good for the departments of which we propose now to take a brief survey in continuation of our last week's article. On entering the room devoted to physics (exclusive of electricity and magnetism), attention is drawn to some aged-looking apparatus on the right. These are the celebrated original Magdeburg hemispheres of Otto von Guericke. They were exhibited by him in 1654 before the Princes of the Empire and the foreign ministers assembled at the Diet of Ratisbon. The force of two teams, each consisting of a dozen horses, made to pull in opposite directions (a portion of the rope is shown) was insufficient to separate the exhausted hemispheres. It was shortly after this date that the Burgomaster of Magdeburg heard of Torricelli's great discovery. The original air-pump of Otto von Guericke is also exhibited. It consisted of a globe of copper, with a stop-cock, to which a pump was fitted. The pump-barrel was entirely immersed in water to render it air-tight. The improvements in the air-pump by Boyle and Hooke, Papin, Hawksbee, and others, can be followed by the actual instruments they made. Among modern improved methods of producing a vacuum, is the pump of M. Deleuil, in which the pistons are solid cylinders of considerable length, without packing or lubricants, and not fitting tightly in the tubes. The internal friction of the air in the narrow space is so great that the rate at which it leaks into the exhausted part of the vessel, is not comparable with the rate at which the pump is exhausting air from the receiver. In the well known air-pump of Sprengel, air is drawn from the vessel to be exhausted into a vertical tube, through the descent of small successive portions of mercury in the latter. Thilorier's apparatus for liquefying carbonic acid, the apparatus used by Dr. Andrews in his researches on continuity of the gaseous and liquid states of matter, and a small model of M. Colladon's new air and gas compressor used for the St. Gothard tunnel, may also be noticed here.

The musical commencement of sound is generally put at about thirty-two (single) vibrations, and the upper limit of audition at about 73,000. Here will be found apparatus illustrating both extremes, including two organ pipes, the individual sounds of which are inaudible, but whose resultant tone or beat is within the limits of hearing. Helmholtz's double siren, and various other instruments connected with his invaluable researches on sound, will repay examination. Among musical instruments we may note some models of ancient Egyptian pipes, from the British Museum and that of Turin, an enharmonic harmonium, tuned according to the division of the octave into fifty-three equal intervals, and the first of the now generally adopted upright pianofortes patented by Robert Wornum in 1811. Mr. Baillie Hamilton contributes a series of apparatus illustrating very instructively the progress of the Æolian principle. The velocity of transmission of sound in water was experimented on by Colladon, on the lake of Geneva, in 1826, and again in 1841, and some of his apparatus is shown in the present section. With the long tube like a speaking trumpet, it is possible, in calm weather, at the distance of more than a hundred kilometres, to hear the strokes on a bell of half a ton weight immersed in the water. Once more, the apparatus is to

[1] Continued from vol. xiii. p. [illegible]

be seen by which Prof. Tyndall recently illustrated the reflection of sound by heated air or vapours; these, being made to stream up through six openings in the long chamber through which the sound is directed, are effectual in stopping its progress.

Of historical interest in the section of Light are some early stereoscopes, comprising that of Sir David Brewster; a camera-obscura said to have belonged to Sir Joshua Reynolds (which, when closed, has the form of a large folio leather-bound book), the original form of Brewster's kaleidoscope made by Bate, in 1815, the first heliostat, invented by Gravesande, &c. The vigour of the young science of spectroscopy is indicated by the fine array of instruments belonging to it, constructed by Steinheil, Browning, and others. There is shown the spectroscopic apparatus which Sir John Herschel used in photographing actions of different parts of the spectrum, and in his investigations on some supposed new elements. For illustrating the theoretical side of the subject of polarised light, various forms of instrument have been devised, the most comprehensive of which is known as the wave machine of Wheatstone; its object is to exhibit the results of the combination of various kinds of vibration meeting at various phases. Instruments based on the three different methods of producing plane polarisation are exhibited; and the various phases of rotatory and other polarisation can be shown simultaneously by means of an instrument which was invented independently by M. Mach and Mr. Spottiswoode. It is known that Wheatstone invented a "polar clock," based on the fact that the light from certain parts of the sky is polarised, and the plane of polarisation depends on the position of the sun; this is included in the collection. It would take too long to refer in detail to the now numerous varieties of photometric apparatus, or the apparatus for observing phosphorescence, fluorescence, and other phenomena connected with light. Several specimens exhibited of the enigmatical radiometers recently devised by Mr. Crookes will doubtless excite lively interest and speculation. In the photographic collection is the first known photograph on glass, taken on precipitated silver chloride by Sir J. Herschel; also the second daguerreotype obtained by Daguerre in 1839. The Woodbury and other processes are fully illustrated.

In the Heat department we cannot allow ourselves to linger at the fine collection of thermometric and other instruments. Among them is a milligrade thermometer, in which the interval between the freezing and boiling points of water is divided into one thousand degrees; it obviates the use of fractions. Wedgwood's pyrometer and Lavoisier's calorimeter are here; and many will feel interested in such apparatus as that by which Tyndall conducted researches on radiant heat, Regnault, De la Rive, and Marcet on the specific heat of gases, or Favre and Silbermann on the heat disengaged in combustion.

In the room devoted to Chemistry we come upon some old apparatus which is of the simplest and even the rudest character; it is a part of that with which John Dalton carried on his classical researches. Most of it was made with his own hands, and the articles here exhibited are chosen as illustrating this fact, and as indicating the genius which, with so insignificant an equipment, was able to produce such great results. The study of pneumatic chemistry was much advanced by the experiments of Black and Cavendish. Black showed that the difference between the caustic and mild alkalies was that the latter contained *fixed air*, a kind of air identical with that obtained from fermenting liquids. Cavendish pointed out the difference between inflammable air, which we now call hydrogen, and fixed air, now known as carbonic acid gas. Black's pneumatic trough and balance, and Cavendish's balance, are among the collection. The latter is rude in exterior but of singular perfection. Here, also, is the balance, belonging to the Royal Institution, which was used by Young, Davy, and Faraday. The researches of Faraday on the condensation and liquefaction of gases are well known, and one may here see the apparatus he employed, along with a number of the original tubes containing gases which he liquefied. Thomas Graham's apparatus, also exhibited, is remarkable, like that of Dalton, for the contrast between its simplicity and the great results that were achieved by means of it. The amateur or professional chemist will doubtless receive not a few happy hints in inspection of the large variety of apparatus connected with qualitative and quantitative analysis; and the comprehensive collection of chemicals contains many novelties. We further note some of the apparatus that Messrs. Lawes and Gilbert have used in their important researches in agricultural chemistry, and they exhibit a case of casts of white Silesian sugar-beet illustrating the influence of different manures on the amount of produce and on the percentages of dry matter and sugar in the roots. The great chemical industries of this country, in fine, are well represented by models of manufactories and by products.

Coming to Biology, we may notice first an interesting collection of old microscopes. Here is the silver microscope that was used by Anthony von Leeuwenhoek, the Dutch philosopher, and probably made by him; also the microscope used by Sir W. Hooker, in his description of the British Jungermanniеæ, &c. The microscopes of Dawson Turner, Robert Brown, Muschenbroek, and others, are also included. There is a compound microscope invented and constructed about the year 1590, by Jansens, the inventor of the telescope. This object, with its tin tube, is one of the most interesting things in the Collection. It is instructive to compare these instruments with their modern neighbours, of which there is a large variety.

The older physiologists obtained only qualitative results from their experiments; but the present generation has witnessed a remarkable advance in the application of instruments of precision to the quantitative determination of the effects of physiological processes. From this point of view a singular interest attaches to the muscle balance, constructed and used just forty years ago, by the eminent anatomist and physiologist who laid the foundations of animal histology. It is intended to demonstrate that muscular contraction takes place in accordance with the laws of elastic bodies, and it may be regarded as the first of the class of instruments referred to. The department contains a rich collection of such instruments; and no better illustration could be taken than the apparatus by which M. Marey has so successfully investigated the phenomena of animal locomotion and other physiological movements. The study of physiological optics has been

greatly cultivated in Germany, and the instruments connected with it (whose nomenclature, by the way, seems unusually bristling and difficult) offer many novel points for consideration. The mechanism of circulation and respiration in the animal subject is studied by means of a variety of delicate apparatus, and we note also some good schematic representations in which the movements are reproduced mechanically. The anatomist and histologist will find many beautifully prepared specimens from animal and plant life.

Leaving the biological section we enter that of geography, geology, and the allied sciences. Here the instruments used by the late Dr. Livingstone in his last journey possess a melancholy interest; they comprise a pocket chronometer, a sextant, hypsometrical boiling apparatus, and three thermometers. Specimens are shown of the dredging, sounding, and other apparatus that have been used on board the *Challenger*, the *Porcupine*, and other exploring vessels. The collection of maps is a large one; in it will be found a selection designed to illustrate the progress of cartography and surveying in India, the maps of the Geological Survey of this country, &c.; also the MS. maps of Livingstone, Burton and Speke, Baker, Stanley, and others. In a glass case may be observed several open log-books. One is Capt. Cook's log of the *Endeavour* in his voyage round the world (1768-71), another is that of one of his later voyages; another, the log of the proceedings of the *Bounty*, including an account of the mutiny. The subject of geology is largely illustrated by sections, maps, models, and specimens. We only note here the illustrations of the recent Sub-Wealden boring. There are numerous fine models in illustration of crystallography, and one of the goniometers exhibited is that of the Abbé Hauy. Among the objects connected with mining may be noted the apparatus constructed by Sir Humphrey Davy in his researches on the safety lamp.

The section of Applied Mechanics, which we have left to the last, might well claim a separate paper or a series of such. We can do no more than briefly refer to the collection of James Watt's models, which indicate, *e.g.*, the progress of his thoughtful labour in connection with the idea of separate condensers, and the expansive working of steam. In Watt's first engine great difficulty was experienced in fitting the piston accurately to the cylinder. Such difficulties exist no longer; and a remarkable example of the skill now attained in metallic constructions is afforded in the fine surface plate lent by Sir J. Whitworth; this is probably the closest approximation to an absolutely plane surface that has yet been realised. Finally, the old "Rocket" constructed by Stephenson in 1829, and the original engine of Henry Bell's steamboat, appear in this collection, the venerable quondam precursors of a great social revolution.

PREJEVALSKY'S MONGOLIA

Mongolia, the Tangut Country, and the Solitudes of Northern Tibet. By Lieut.-Colonel N. Prejevalsky, Translated by E. Delmar Morgan, F.R.G.S. With Introduction and Notes by Colonel Henry Yule, C.B. (Sampson Low and Co., 1876.)

WE have had occasion once or twice to refer briefly to Col. Prejevalsky's travels in Eastern High Asia, and some of our readers may have seen more or less detailed notices of his journey in the German and English geographical journals. These have been sufficient to show that the narrative of the Russian officer is of unusual value, and we are therefore thankful that not much time has been lost in making it accessible to the English public, to which Russian is practically an unknown tongue. The two volumes before us, however, contain only Col. Prejevalsky's general account of his expedition; and we regret that there seems to be no intention of making the special scientific results accessible to English readers. Judging from what is contained in the two volumes before us, these must be of the highest importance, and we hope that by some means they will be made known to English men of science.

The present translation has been brought out with great care. Mr. Delmar Morgan has put the narrative into clear and idiomatic English, which, we have reason to believe, faithfully represents the original Russian. He has, moreover, added to the value of the narrative for English readers by numerous supplementary and foot notes. We consider that both Col. Prejevalsky and the English reader are particularly fortunate in having the advantage of Col. Yule's knowledge to supplement and correct the original narrative. In an introduction he connects the journey of the Russian officer with those of previous explorers in Central and Eastern Asia, and especially with that of the well-known Huc and his companion Gabet. Considerable discredit has been thrown on the narrative of Huc, but Col. Yule shows that in the main it may be regarded as trustworthy, allowance being made for the missionary's love of exaggeration and his desire to produce effect. Prejevalsky's journey from Pekin to the south-west into Tibet coincided to some extent with that of Huc, and the former on several occasions impugns the accuracy, if not the veracity, of the latter. Those who are familiar with the old Abbé's delightful narrative will be glad to know that so great an authority as Col. Yule thinks that after all he is in the main trustworthy. Col. Yule's numerous notes will, moreover, be found to add much to the value of the work, both as supplementary to the main narrative and as corrective of occasional statements by Col. Prejevalsky arising from imperfect knowledge or rashness. This narrative Col. Yule shows, is an additional confirmation of the remarkable accuracy of that of Marco Polo.

The starting-point of Col. Prejevalsky's expedition was the town of Kiakhta, on the border of Siberia and Northern Mongolia, from which the small party set out in November, 1870, and returned to it after having done three years' hard and fruitful work, in October, 1873. The expedition seems to have been essentially a Government one, sent out at the instigation of the Russian Geographical Society. It is, therefore, difficult to understand how Col. Prejevalsky should have been so seriously hampered from want of sufficient funds. Yet so it was; the resources at the leader's command were a mere pittance as compared with the magnitude of the undertaking. The entire party consisted only of the Colonel, a companion, and two Cossacks, and the instrumental equipment was the most meagre possible. All things considered, it is marvellous that the results achieved were so many and so valuable. From Kiakhta the party went by Urga across the desert of Gobi, probably the dreariest desert in the world, to

Kalgan, and hence to Pekin. From Pekin a preliminary tour was made to the north, to Lake Dalai-nor, one object being to observe the spring flight of the birds of passage. This is a subject in which Col. Prejevalsky takes great interest, and throughout the whole extent of his journey he continued to make observations on the migrations of birds, and the present volumes contain many valuable notes on the subject. Lake Dalai-nor, which like many other lakes in this region, is salt, is described as a great rendezvous for migratory birds. The flight and habits of these birds are described fully in the more strictly scientific part of Col. Prejevalsky's account of the expedition, which is not included in the present translation. There is, however, a list of the various birds observed at this lake. In this, as in subsequent parts of his journey, Col. Prejevalsky noted as far as possible all the important features and products of the country as he proceeded. Surveying, however, was attended with many difficulties, on account of the suspicions of the natives, Chinese and Mongols, and it was only by stealth and by resorting to various artifices that Col. Prejevalsky could make use of his note-books. Another cause of difficulty and especially of delay was the insurrection of the Chinese Mohammedans, who had overrun and devastated much of the country through which Col. Prejevalsky's expedition passed.

On returning to Kalgan the expedition commenced the serious part of the undertaking, proceeding westwards by the In-shan Mountains, and crossing the Hoang-ho at Bauta, near the centre of its great northern bend. Proceeding along the left bank of the river through the country of the Ordos, the party recrossed the Hoang-ho at Ding-hu, into the Ala-shan country, and were well received by the prince at Din-yuan-ing. A number of days were spent here hunting and exploring among the Ala-shan mountains; but want of funds compelled the expedition to return to Kalgan. The return route was along the left side of the northern bend of the Hoang-ho, through the Khara-narin-ula mountains, where the cold experienced was quite Arctic. After staying a couple of months at Kalgan, the party again set out, this time fortunately much better equipped. They followed

Fig. 1.—The Gobi Plateau

pretty much the same route as on their return, until they again reached Din-yuan-ing, where their reception was by no means so hospitable as on the previous occasion. Fortunately they fell in here with a caravan of Tangutans bound for the Lama Monastery of Chobsen, within a short distance of Lake Koko-nor, the great goal of Col. Prejevalsky's efforts. After many attempts to prevent it on the part of the prince of Din-yuan-ing, the party set out with the Tangutan caravan, and, notwithstanding the country being overrun with the Dungans or Mohammedan rebels, Chobsen was safely reached. This monastery is about forty miles north of Sining-fu, on the south-western slope of the mountains bordering on the Tatung river, which lie to the north-east of Lake Koko-nor, and form part of the southern boundary of the Desert of Gobi. Among these mountains a considerable time was spent in hunting and making collections in natural history. The party "also investigated, *de visu*, for the first time it is believed in modern history, the famous rhubarb plant in its native region." The inadequacy of his means compelled Col. Prejevalsky reluctantly to give up the idea of penetrating as far as Lhassa. The basin of Lake Koko-nor was, however, explored, and the travellers pushed on to the south-west, through the region of Tsaidam, which is described as a vast salt-marsh covered with reeds, as if recently the bed of a great lake, and is said by the Chinese to stretch west and north to Lake Lob. Col. Prejevalsky proceeded as far as the lofty and uninhabited desert of Northern Tibet, turning at the upper stream of the great Yang-tse-Kiang, here called by the Mongols the Murui-ussu.

The party retraced their steps leisurely as far as Din-yuan-ing, where they arrived in a most worn and ragged condition. After a rest here they set out to attempt what was probably the most arduous part of their undertaking, the crossing of the heart of the great desert of Gobi from south to north, a feat never before attempted by any European. "This desert is so terrible, that in comparison with it the desert of Northern Tibet may be called fruitful. There, at all events, you may find water and good pasture-land in the valleys; here there is neither the one nor the other, not even a single oasis;

everywhere the silence of the Valley of Death." Kiakhta was reached on October 1, 1873.

Such is a very brief outline of the route traversed by the small expedition under Col. Prejevalsky. It gives no idea of the amount of work done, and the many difficulties which had to be overcome. Though the Colonel had a pass from the Chinese Government, it was not of much use to him. At almost every stage obstructions were thrown in his way, and had the party not been able to obtain a living by their guns they would either have had to starve or turn back. The whole distance traversed was upwards of 7,400 miles.

Col. Prejevalsky's object was not simply to get over a certain amount of ground. In many respects he is well qualified to conduct a scientific exploring expedition. Not only is he skilled in all kinds of surveying work necessary to map a country, but has evidently a good

FIG. 2 — Mongol Girl.

knowledge of geology, and is above all an accomplished zoologist and botanist. At every stage he stops to describe deliberately the natural features of the region, its inhabitants, its history, and to give long lists of the animals and plants collected. Some idea of the importance of the expedition from a scientific point of view may be learned from the fact that the plants collected amounted to 5,000 specimens, representing upwards of 500 species, of which a fifth are new. But especially important was the booty in zoology, which is Prejevalsky's own specialty, for this included thirty-seven large and ninety smaller mammals, 1,000 specimens of birds, embracing 300 species, 80 specimens of reptiles and fish, and 3,500 of insects.

It would be impossible within the space of a notice like the present to give any adequate idea of the kind and amount of information contained in these volumes. No such keen-sighted and accomplished traveller has been over the same ground before. We shall endeavour to indicate a few of the points referred to. In the Introduction, besides the matters already referred to, Col. Yule adduces strong proofs for the existence of the wild camel on the north-west borders of China, and gives a few valuable notes on the real nature of Tibetan Lamaism. The Gobi desert, both in its eastern and central positions, is at last described with something like adequacy; it is probably one of the dreariest tracks on the face of the earth. One of the strong features of the book is its ethnology; all the groups of people passed through are described in detail. A whole chapter is devoted to the Mongols, containing minute particulars as to their manners and customs. In the same way many important notes are given concerning the Chakhars, the Ordos, the Oluet or Ala-shan Mongols, the Tangutans, and the Dungans or Tungani. A large space is devoted to an account of the Mongol camel, in which some points are brought out that will be new to many; and the Argali (*Ovis argali*) and its habits are described in considerable detail, as also the White-breasted Argali of Northern Tibet (*Ovis poli*). Geographers will find some valuable information concerning the present course of the northern bend of the Hoang-ho, which is many miles south of that which is found on many modern maps. There seems to be now only one main channel, the two northern ones being dry. Many evidences are adduced to show that much of the region through which the expedition travelled was at one time an inland sea; most of the lakes are salt, and the country of Ala-shan seems to be one great desert of sand and clay mixed with salt. Col. Prejevalsky mentions an interesting fact showing how particular may grow into general terms. He tells us that the Mongols apply the term "Russian" to all Europeans, and affix "French" or "English" as they wish to designate either of these nations. They also believe the latter to be vassals and tributaries of the former, and Col. Prejevalsky mentions several circumstances tending to show the great opinion of Russian power held by the inhabitants of Central Asia. Lake Koko-nor and the region around it, as well as the province of Kan-su generally, in which the expedition spent many months, are described in all their aspects with the greatest minuteness.

But it is needless to attempt to give any adequate idea of the contents of these two volumes; they are a perfect mine of information about the whole of the little-known region visited by Col. Prejevalsky and his companions. The work is a fine example of what the narrative of a scientific exploring expedition should be, and although Col. Prejevalsky delivers "a plain unvarnished tale," his work is full of interest from beginning to end, even for the omnivorous "general reader." The map which accompanies the work is on a large scale and is filled in with such minuteness as to present a satisfactory bird's-eye view of the principal results of the expedition, and the illustrations are both attractive and useful. To quote the words of Col. Yule, "the journey and its acquisitions form a remarkable example of resolution and persistence amid long-continued toil, hardship, and difficulty of every kind, of which Russia may well be proud."

THE MOABITE QUESTION

Die Aechtheit der Moabitischen Alterthümer Geprüft. Von Prof. E. Kautzsch und Prof. A Socin. (Strassburg, 1876.)

Moabitisch oder Selimisch? Die Frage der Moabitischen Alterthumer neu untersucht. Von Adolf Koch. (Stuttgart, 1876.)

IT was perfectly natural that the discovery in 1868 of the famous Moabite Stone, which created such a sensation all over the civilised world, should have made literary and scientific men wish to explore the dangerous eastern side of the Dead Sea. Hence, when Dr. Ginsburg set forth the importance of an expedition to Moab in his paper before the Geographical Section of the British Association (Liverpool, 1870), the Association willingly granted 100*l.* towards the contemplated expedition, and in the following year supplemented this grant by another 100*l.* But this expedition which took place in the beginning of 1872, contributed next to nothing to our former knowledge of the trans-Jordanic regions. The only thing which it did effect was indirectly to encourage the designing Arabs in their production of Moabite antiquities.

Travellers in Syria well know the pertinacity with which they are pursued by the Arabs, who in every locality offer all sorts of relics for *Bakshish.* Hitherto these antiquities were principally confined to coins, chiefly of course shekels and half-shekels, bronzes, armoury, gems, wooden utensils, and pictures from the time of Christ, made by eye-witnesses of the scenes described in the Gospels. Since the discovery of the Sinaitic Codex and the Moabite Stone, however, which fetched so high a price, and which have created a perfect rage among a certain class of itinerant scholars for acquiring like precious relics, the finds have in a marvellous way corresponded to the desires of the inquiring travellers. A few months after the Tristram-Ginsburg expedition, in search for antiquities and specimens of natural history in Moab, was fitted out on such a pompous scale at Jerusalem, where the object of the journey became at once blazoned about, a number of inscribed stones were discovered, among which was one recording Psalm cxvii. As Herr Weser, the Chaplain to the German Consulate and Colony at Jerusalem, is the principal literary and scientific agent, who not only tested these Moabite antiquities on the spot, but also forwarded drawings of them to Germany and finally, with Prof. Schlottmann, induced the Prussian Government to purchase them and deposit them in the Berlin Museum, we cannot do better than give this learned Divine's own words :—"The fourth stone is to me the most interesting. It contains Psalm cxvii. in magnificent ancient Hebrew characters, similar to those on the stone of Mesha. Who knows but that this stone contains the very original from which the Psalm was read and adopted into the collection of Psalms." (*Die Aechtheit*, p. 13.)

As the famous Moabite stone records a biblical event, parallel to the one recorded in 2 Kings, iii., a discovery was at once made which should completely eclipse the narrative of this lapidary document, and at the same time vie with the celebrated Codex Sinaiticus. Prof. Scholz, who has been working for several years on the Massoretic text of Jeremiah in its relation to the Greek Septuagint, was in Jerusalem in 1870. Of course he visited Shapira's Antiquarian establishment, and naturally enough inquired after MSS. of the Hebrew Scriptures, when lo, and behold! this honest merchant showed the Professor, amongst other ancient Biblical documents, a remarkable manuscript of the very prophet on which Dr. Scholz was commenting. Here again we must give the words of the learned German, but this time no less a person than "Professor of Exegesis of the Old Testament and the Biblical Oriental Languages at the University of Wurzburg." In his work on Jeremiah which appeared at Regensburg, 1875, this learned Professor remarks :—"Perhaps it is not beyond all hope that science will come into possession of the text of Jeremiah which the Septuagint translated. In 1870 the author visited the bookseller Shapira at Jerusalem, who showed him a manuscript of Jeremiah, written very beautifully, without vowels and accents, which he averred corresponded to the translation of the Septuagint. When I called again, after a few days, it was sold to an Englishman. According to Herr Shapira, who declared that he possessed evidence for his statement, the MS. is of about the time of Christ."

But though *savans* like Pastor Weser and Prof. Scholz were easily deceived by the Psalm Stone and the Jeremiah MS., yet it was soon found that to continue discoveries in the department of Old Testament documents was both unprofitable and hazardous for very simple reasons. It is well known, even at Jerusalem, that no manuscript of any portion of the Hebrew Bible prior to A.D. 800 has as yet been discovered. If a MS. pretending to be of even 200–800 A D. were to be forthcoming, the science of palæography is now so definite and unerring that it would be detected at once. Nor could discoveries of any lapidary documents which exhibited a continuous narrative in any known Semitic dialect be safe, since the science of language is now so exact that an attempt to impose upon philology or palæography is almost certain to break down. Hence if the rage for inscriptions created by the discovery of the Moabite stone, and increased by the Tristram-Ginsburg Moabite expedition, which left England at the beginning of January, 1872, was at all to be gratified with any chance of safety and profit, nothing was left to the dealers in antiquities at Jerusalem but to open up new mines. This was easily done

Selim, who was in the service of the Duc de Luynes and M. de Saulcy, when these French *savans* travelled in Moab, and who had also been employed by M. Ganneau to negotiate with the Arabs at Dibon for the Moabite stone, was out of employment. Such an indication of Providence was too plain to be mistaken by good Shapira. Accordingly Mr. Shapira employed him at a monthly salary, to go to Moab in search of antiquities, and in addition to his fixed pay promised him a premium on every discovery. With such a temptation before him, this unmitigated rascal whom Drake describes as "a well-known scoundrel and forger," set out for Moab. No wonder that the search conducted by such a man and with such prospects, was eminently productive. In May, 1872, that is about a month or six weeks after the Tristram-Ginsburg expedition returned from Moab, a few specimens of pottery appeared at Mr. Shapira's depôt. In July the collection increased to 600 pieces, in October

to 700 pieces, and soon after it mounted up to 1,800 pieces. Shapira was now enabled to divide the finds into three collections, as follows :—

Collection 1. Containing 911 pieces, 465 inscribed ;
" 2. Containing 493 pieces, 60 inscribed ; and
" 3. Containing 410 pieces, 68 inscribed.

These collections embrace urns and pots, figures, idols, and birds partly entire and partly broken. Some of these antiquities have found their way to Stuttgart, but the bulk, consisting of the choicest specimens and numbering in all about 1,700 objects, have been bought from Shapira by the Prussian Government for 22,000 thalers = 3,300*l*., and are now deposited in the Berlin Museum. Prof. Koch, the author of the second treatise under review, who visited Shapira's depôt in 1875, tells us that this dealer has now another collection consisting of no less than 724 pieces, of which 133 are inscribed, containing in all 4604 letters (Dr. Koch, p. 3-22).

The interest of science in these discoveries is immense. If these antiquities could be proved to be genuine, their contribution to ethnology, history, mythology, philology, and palæography could hardly be overrated. They would exhibit to us the history of the mental and moral condition of a country, which has played an important part in ancient times, and about which we know next to nothing from the incidental and fragmentary allusions in the Old Testament. Literary and scientific opinion in England has almost unanimously declared these finds as forgeries. In Germany, however, where so many of the articles themselves are deposited, not a few men of eminent scientific attainments believe in their genuineness. Some of the results of these discoveries have even been embodied in no less a work than Riehm's "Dictionary of Biblical Antiquities," the distinguished editor of which professes to exclude everything that is controvertible, thus stamping this contribution as *veritable history*. The divided opinion in Germany may moreover be seen from the fact that of the two treatises which head this article, No. 1, by Professors Kautzsch and Socin, is against, whilst No. 2, by Prof. Koch is for the genuineness of these discoveries. After a careful study of the question, we shall endeavour to describe as briefly as possible the arguments adduced by Professors Kautzsch and Socin against the finds, with which we fully agree, unless those scholars who believe in the antiquities can produce more conclusive evidence.

1. The Duc de Luynes, M. de Saulcy, Palmer and Drake, Tristram and Ginsburg have more or less searched the country, and could find no traces of such articles, though the Moabites were perfectly alive to the value which Europeans set upon the most insignificant relic of any kind ; and though these Arabs, as we ourselves can testify, scraped together and offered for sale the most contemptible objects bearing the semblance of a relic.

2. In consequence of the large sum which was paid for the original Moabite stone, manufactories were opened in Jerusalem and elsewhere which produced inscribed stones, pottery, and other relics. That such forgeries were constantly forthcoming is admitted even by those who believe in the genuineness of the pottery in question. Indeed, Prof. Koch himself gives a detailed description of some of them (p. 67, &c.).

3. There can be no doubt that Selim was perfectly qualified to design these articles, both by his previous occupation as a Christian artist of sacred pictures, and by his subsequent training under the Duc de Luynes, M. de Saulcy, and M. Ganneau. That such an undertaking would be in perfect harmony with his well-known character as scamp and wholesale forger will likewise not be questioned.

4. The extraordinary rapidity with which these Moabite antiquities were supplied by Selim, when nothing of the kind could be found before, goes far to show that they were made under his direction. Only a few months before, we ourselves visited and searched some of the spots where Selim pretends to have made these discoveries, and could find no trace of such antiquities. The American exploration party have been there since (1873), and could likewise find nothing.

5. Drake and Ganneau traced the spot where these antiquities were made, and declared that they were manufactured in Jerusalem, transported to Moab, where they were buried, and then exhumed and sold to Shapira.

6. The intermixture of the earliest Phœnician with later forms of letters of which the inscriptions are made up, betrays the clumsy and unskilful manner in which they have been put together. That Selim and his companions knew these characters is perfectly certain. Not only did Selim copy for Ganneau some of the veritable Moabite inscription, but he and others possessed a facsimile of the inscription ; and we ourselves have seen in the hands of Mr. Shapira and other dealers in Jerusalem parts of the *Transactions* of the German Oriental Society, Levy's "Phœnizische Studien," with fac similes of various inscriptions, the fac-simile of the Eshmunazar Inscription, and the leaf from Madden's "History of Jewish Coins," which gives the different Semitic alphabets. These were carefully studied in Jerusalem.

7. But what confirms us in the belief that these inscriptions have been produced by individuals who simply knew the ancient alphabets but did not know how to compile a single sentence is the fact that, even under the immense pressure of Prof. Schlottman's great learning, the inscriptions have yielded no sense. So eminent an epigraphist, as the late Rödiger was forced to say, "that though these extensive Moabite texts are mostly written in characters, the value of which is perfectly fixed and certain, no connected sense can be discovered in them." ("Zeitschrift der Deutschen Morganlandischen Gesellschaft," xxvi. 817.) The force of this remark will be felt all the more when it is remembered that the language of the real Moabite stone can be understood by every Semitic scholar. Prof. Schlottman, who is too scientific an epigraphist not to see the strength of this argument is obliged to resort to the expedient that the inscriptions contain "strong abbreviations and permutations of letters."

The most extraordinary part of the controversy is the indecision about the clay of the pottery. We should have thought there could not have been two opinions among experts upon this question. If the authorities in the keramic art cannot definitely decide whether a pot or urn is three years or three thousand years old, there is little encouragement for those who have lately paid such enormous prices for old China. But whatever be the result of the controversy, the treatises of Professors

Kautzsch, Socin, and Koch which it has elicited will remain valuable contributions to palæography, and if it should call forth any more such solid disquisitions, science will be permanently benefited.

HOOKER'S "PRIMER OF BOTANY"

Science Primers. Edited by Professors Huxley, Roscoe, and Balfour Stewart.—"Botany." By Dr. J. D. Hooker, C.B., P.R.S. (London: Macmillan and Co., 1876.)

It is now almost universally admitted that the study of botany may be made an excellent training for children; but the extent of the subject is so great, and the phraseology has become so overwhelmed with technical terms that even those who have been the most anxious to see the science generally introduced into our schools as a branch of education, are much perplexed when called upon to determine in what way it can best be taught. Some think it most prudent to confine the attention of children to such points as may be observed with the unaided eye, or at any rate to such points as only require the help of an ordinary magnifying-glass; hence they limit the teaching of botany to a study of the more conspicuous parts of the higher groups of vegetable life, and leave the study of physiology and histology to a more advanced age. There is, no doubt, much that can be said in favour of this view, for in order to become fully acquainted with these branches of botany a much greater experience and skill in manipulation and experiment are required, as well as the use of high magnifying powers, than, it is quite certain, a child can be expected to possess. At the same time this limitation to so small a portion of botanical science has the tendency to produce in the mind contracted ideas respecting the true scope of the subject; for to a large extent it only admits of facts being heaped upon facts, without their proper connection one with another being made manifest. It is owing to this want of concatenation in the teaching that has led many to think less highly of botany as a branch of education than they otherwise might have done, and that its introduction into schools has not met with so much success as its more sanguine advocates could have wished to see.

The "Primer" of Botany by Dr. Hooker will go far to remove these difficulties, which have hitherto stood in the way of a more successful treatment of the subject; for in the simplest language, and with an absence of all technical terms but such as are absolutely necessary for a proper comprehension of the subject—and which, when they do occur, are always fully explained—the pupil is introduced to all the most important facts connected with structural and physiological botany. These facts, by means of a judicious arrangement and proper explanations, are made to exhibit their mutual dependence upon one another, and the work thus forms a continuous argument from beginning to end. Although the book contains only 112 pages, and is profusely illustrated, there is hardly a point in structure or physiology that is not touched upon, and so far as the scope of the book will allow, fully explained. A further very noticeable characteristic of the "Primer" is that the pupil is instructed to draw conclusions from information derived from observation founded upon experiment as well as from direct observation.

To teachers the "Primer" will be of inestimable value, and not only because of the simplicity of the language and the clearness with which the subject matter is treated, but also on account of its coming from the highest authority, and so furnishing positive information as to the most suitable methods of teaching the science of botany, and for the want of which the instruction given in schools has hitherto been too often of a most capricious description. Again, those who have the formation or management of gardens, set aside for botanical purposes, entrusted to them, will find the list of plants at the end of the book extremely useful, as it contains those which experience has shown to afford the best examples of the particular characters it is desirable to illustrate; they are also such as may be readily procured and easily grown.

If the "Primer" has long been looked for, the high expectations which have been raised are not doomed to be disappointed, and it may be confidently anticipated that its introduction into schools will determine very largely the direction which the teaching of botany in this country will take for the future.

M. A. Lawson

OUR BOOK SHELF

Aventures Aériennes et Expériences Memorables des Grands Aéronautes. Par W. de Fonvielle. Ouvrage orné de 40 gravures. (Paris: E. Plon, 1876.)

M. de Fonvielle's name is no doubt familiar to our readers as that of an experienced scientific aeronaut and writer on aeronautics. In the work before us he has traced in an interesting and instructive manner the history of ballooning from the first rude attempts to rise in the air, down to the elaborate experiments and machines which have been devised at the present day. He has evidently spent considerable pains to obtain a complete knowledge of the history and methods of ballooning, and his scientific knowledge enables him to point out in the many experiments which have been made, the causes of failure or success. The work is evidently meant mainly for popular reading, and those who understand French will find it full of interest. The author attempts to show how practically to utilise a discovery which up to the present time has produced few practical results. He is quite opposed to all the fantastical projects which have been proposed and tried in aeronautics, and treats his subject, on the whole, in a sensible and moderate fashion, showing that those chimerical schemes have been really hindrances to the improvement of aërial navigation. He shows that important meteorological results might be obtained by properly organised ascents, and that indeed in this respect results of some importance have already been obtained. The numerous illustrations are interesting, and altogether the work may be regarded as an important contribution to the history of aeronautics.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

New Laurentian Fossil

Mr. James Thomson, of Glasgow, who has been for some years on the out-look for fossils in the Laurentian rocks of Scotland, and has searched parts of Argyleshire, Inverness-shire, Ross-shire, and Caithness with this object, has lately been rewarded by the discovery, in the neighbourhood of Tarbert,

Harris, of what is regarded by every Palæontologist who has seen the specimen as an unquestionable *organism*. It forms part of a limestone bed intercalated with dark grey shale, and occurs in the midst of highly metamorphic rocks (among them a graphite granite), which were regarded by Sir Roderick Murchison as of Laurentian age, and which have ever since passed as such—no doubt being entertained as to their antiquity by Dr. Heddle, of St. Andrew's, who has geologised over the whole of Harris.

Judging from the sections which Mr. Thomson has forwarded to me, the fabric seems to have consisted of superposed layers of calcareous shell-substance, whose continuity is frequently interrupted; the spaces between these layers, which are much thinner than the lamellæ themselves, being irregularly and imperfectly divided (very much as in Eozoon) into separate chambers, which are filled up with calcite. The state of preservation of the fossil thus corresponds exactly with that of the Silurian *Stromatopora*, to which, indeed, it bears a strong general resemblance, except in the larger proportion borne by the solid fabric to the chambers it encloses. The shelly layers are as distinct in character from the calcite contents of the chambers, as are those of the Nummulites of the pyramid-limestone, with which they agree in their remarkable hardness, corresponding with that of porcellanous shell. Altogether I have no hesitation in concurring with Prof. H. A. Nicholson, Prof. Geikie, and Mr. Etheridge in affirming it to be so unmistakeably organic, that, if it be claimed by mineralogists as a "rock-structure," a large number of universally-accepted fossils will have to go along with it. As it is *essentially calcareous* in its composition, there is no room for the hypothesis of its production by the process of "mineral segregation," which is maintained by certain Mineralogists (others of at least equal eminence, however, entirely dissenting from them) to have been adequate to the production of the alternating layers of serpentine and calcareous shell-substance in the Canadian *Eozoon*. And though mineralogical analysis might not improbably detect small particles of various minerals in its substance, their presence no more establishes its claim to be regarded as a mere rock-structure, than does the presence of siliceous films (probably replacing the soft parts of the animal) in a piece of coral-limestone.

Not having made any other than a general examination of the structure of the Harris specimen, I do not feel able to give a positive opinion upon its affinities; and it may be that these may long remain doubtful. But this doubt no more constitutes an adequate reason for refusing to accept its organic origin, than it does in the case of *Stromatopora*; which no Mineralogist that I ever heard of claims as a mineral, though the Zoologist cannot say with certainty whether it is a foraminifer, a sponge, a coral, or a polyzoary. It is to be borne in mind that in very few Palæozoic fossils is there a *precise* conformity to any existing type; and such conformity is, of course, still less to be expected in a Laurentian than in a Silurian fossil.

It is not a little singular that I should have received about the same time from Prof. Mobius of Kiel, specimens of a new Foraminiferal organism, discovered by him in 1874 on a coral reef off Mauritius; which presents more resemblance in its spreading and encrusting mode of growth to the indefinite expansions of *Eozoon* and *Stromatopora*, than does any Foraminiferal type previously known. Truly, as I have before had occasion to say, "there is no limit to the possibilities of Foraminifera."

I have only to add, in regard to the Harris fossil, that the further prosecution of the inquiry into its structure and relations has been placed by Mr. Thomson in the able hands of Prof. H. Alleyne Nicholson, and that it is at the joint request of these two gentlemen that I make the present communication.

WILLIAM B. CARPENTER

The Warm Rain Band in the Daylight Spectrum

ON taking my accustomed spectroscopic peep at the sky today, through a little garret window in the Royal Observatory here, I was instantly struck with the presence of the same dark band in the spectrum to which I called your attention last summer twice over (vol. xii. pp. 231, 251).

The band was very faint, but it was there, and this was its first appearance, to me at least, during the present year. I have not indeed been so persevering in that sort of observation as I perhaps should have been if furnished with better instruments, yet for weeks and weeks past I *have* scanned the sky, not only when it was heavily clouded, but also when rain was actually falling with west, south-west, and north-east winds, and sometimes during dense, wet fogs, when very little daylight at all was left, and under some preternaturally low barometric pressures. Yet, under all these circumstances, I put the spectroscope back into its box after each trial with the assurance that no rain-band had then been shown by it. This morning, however, and under a barometer not low, viz., 29·8 British inches, the band exhibited itself instantly; and on my going out to look at the direction of the wind, behold it was from the south-east. Wherefore I had no scruple in informing a professor whom I met in the afternoon at the College, and who, after his day's work there was going home to indulge in the amenities of horticulture, that his flowers were certain of presently having the luxury of *warm rain*.

Such rain, too, did begin, within an hour of that interview, with large heavy drops, and the evening has ended with almost a soaking rain.

It is rather too soon to attempt fully to describe the spectrum appearance, much less to explain it, before I have had the privilege of using anything in the way of a notable spectroscope upon it. But having been already written to for some practical information, even from St. Petersburg (where NATURE is evidently read with attention), I may remark that the nebulous band character of the phenomenon is simply a result of want of light; for when the quality to give the band was present in the air, and the sun has been prevailed on to shine for a moment through that air, and into the spectroscope, the band was instantly resolved into a group, or groups, of fine and sharp black lines, exquisitely visible.

But as the sun is seldom to be seen in any weather threatening rain, whether warm or cold, in fact, cannot be consulted precisely at those times when he is most wanted, it is better to restrict such pluvio-spectroscopy to ordinary sky, *i.e.*, clouds or air; and if possible in a polar direction, so as to be equally distant from the sun, whether visible or not, all the day through; and not too low, in altitude, lest smoke, local moisture, and other impurities have too great and variable an influence. The Observatory garret-window here, I regret to say, is not so unexceptionably situated in azimuth as it might be, for it looks out straight to the south, and the angle at which I usually look through it, on being measured to-day, turned out to be 23°.

Nevertheless, at that altitude, keeping to it steadily on all occasions, and in that direction, avoiding always the garish spectra of actual sunshine, and depending not on any particular and absolute spectrum representation in the published maps of other observers, but chiefly or entirely attending to the *differences* observed by myself from day to day in my own manner with my own little tube, there was no difficulty in instantly pronouncing this morning that there was something in the air through which daylight was then passing different from what it has been for several months past.

Whether that something is only watery vapour at a high temperature (seeing that watery vapour at a low temperature does not produce it), or whether the air is carrying something else with it, giving to the south-east winds here a slight approach to the quality of the siroccos of the Mediterranean, which are often transfused with fine dust along with their warm rain, and do produce some very noteworthy markings in the spectrum, is a matter for further and wider research by those who are instrumentally and financially better able to follow it up; and who should therefore be implored in the present state and needs of science to perform their part without further delay.

PIAZZI SMYTH,

Edinburgh, April 24 Astronomer-Royal for Scotland

Limestone Makers

MR. J. MUNRO'S interesting letter and sketch which appeared in NATURE, vol. xiii. p. 510, show how much may be done in the Tropics by ordinary observers towards elucidating many geological problems. His sketch is that of one of the genus Corallina, a member of the Florideæ, and it is a very common lime maker at the Bermudas. Although Mr. Munro will not find a list of the different limestone makers in books, still in the vast unwritten knowledge of geology it is well known that shells, foraminifera, serpulæ in numbers, and huge masses of Nullipores, besides the corallines, contribute to the coral stock.

The corallines present many and varied forms on our own coasts, but their beauty and construction are remarkable in the warm waters of the Gulf Stream and Caribbean Sea. Through the kindness of Mr. Henry Lee I have lately had the opportunity of examining the newly-started growth of the common *Corallines officinalis*, but curious as its cellular development is, it is

a dwarf in comparison with those seen by Mr. Munro and Mr. Quin. Doubtless the broken-down and pulverised corallines fill up many a crack in the reef's limestone. Should Mr. Munro be desirous of seeing some of his old West Indian corallines, I shall be glad to show him some microscopical results of work upon them. P. MARTIN DUNCAN

Geological Society, May 1

History of Magnetism

A PARAGRAPH in the article on "The Early History of Magnetism," in your last number, contains a passage which requires, I think, a note of explanation. The writer says: "A Latin letter ascribed to Peter Adsiger, 1269, preserved among the manuscripts of the University of Leyden, contains the following remark on the declination of the needle . . ." Now Humboldt, on the authority of Libri, denies the existence of the passage in the Leyden MSS., affirming that it is only an interpolation in a Paris copy. But what is of more importance, he also states that the title of the letter is "Epistola Pêtri P. de Maricourt *ad Sigernum* de Foucoucourt." E. Walker, in his well-known essay on Magnetism, refers to Cavallo as quoting the supposed letter of Adsiger. S. J. PERRY

Meteorological Society

WHILE thanking you for your friendly notice of the Annual Report of this Society, I trust you will allow me to state that we have not made "the mistake in science regarding the height of the thermometers above the ground," as very naturally imagined by you from the matter not having been mentioned. The fact is, we have been unusually strict on that point; our thermometers are all 4 feet (within, perhaps, 2 in. + or --), and as the uniformity was so strict, it was considered useless to repeat the statement for each station, and so, finally, it escaped mention altogether in the printed abstract. Of course the question (Report, p. 52), "What is the height of the bulbs above grass?" is duly answered on the MS. inspection forms deposited in the library of the Society.

May I, in conclusion, express the hope that the example which we have set by publishing the lithograph ground-plans, and which you so highly approve, may be generally followed both in this country and abroad? G. J. SYMONS

Meteorological Society, 30, Great George Street,
Westminster, S.W., April 28

Destruction of Flowers by Birds

THE enclosed blossoms of the common "wild" cherry (*Prunus avium*, L.) have been mutilated in a precisely similar manner with those of the blackthorn noticed about a year ago in NATURE (vol. xii. p. 26), the petals and stamens still adhering to the separated limb of the calyx, which has been cut through at the exact level of the ovary, which has perhaps been the object of attack. Orchard trees in the neighbourhood from the same stock have also suffered to a serious extent, but the wall-cherries (*P. cerasus*, L.), which are later in flowering, have hitherto been untouched. R. A. PRYOR

Hatfield, May 2

OUR ASTRONOMICAL COLUMN

THE NEBULA IN ORION.—M. Tisserand, Director of the Observatory at Toulouse, commenced on Feb. 17 of the present year, a close examination of the small stars in the vicinity of the trapezium in the great nebula of Orion, with the Foucault telescope of $0^{m}\cdot80$ aperture, which had been completely mounted at the beginning of the same month. To facilitate the study of this region, which it is intended shall form part of the work with this fine instrument, a chart was prepared on a large scale containing the 155 stars, the positions of which relatively to θ^1 Orionis, were determined by M. O. Struve (*Observations de la Grande Nebuleuse d'Orion* in the St. Petersburg Memoirs, vol. v.); of these 155 stars it may be mentioned that 150 occur in Sir John Herschel's list in the volume of observations made at the Cape of Good Hope. Especial attention was directed at Toulouse during the few weeks that the nebula could be observed in the last season, to the stars which M. O. Struve had indicated as variable. The star II ($\Delta\alpha$ . . $-7''\cdot3$, $\Delta\delta$ . . $-27''\cdot6$) which is not in Herschel's catalogue, was noted on Feb. 17 and 21 at the extreme limit of visibility: on following days, when the sky was more transparent, it could not be discerned; at maximum according to Struve this star is of the twelfth magnitude, the smallest star which can be distinctly seen in the Pulkowa refractor being considered 13·5—a very different scale of magnitude, it will be remarked, from that of Bessel; No. 78 ($\Delta\alpha$ . . . $+34''\cdot5$, $\Delta\delta$ . . . $+9''\cdot7$), varying, according to Struve, from 12·5 to invisibility, was not discerned; No. 75 ($\Delta\alpha$ . . . $+21''\cdot3$, $\Delta\delta$ . . . $+39''\cdot2$) was 14-15 on March 14; Tisserand found No. V. of the Pulkowa list ($\Delta\alpha$ . . . $+378''\cdot3$, $\Delta\delta$ . . . $+66''\cdot3$) extremely faint on Feb. 24, and quite invisible subsequently, whence he concludes this star to be also variable, and that its non-insertion by Herschel may have arisen from its being at a minimum at the epoch of his observations.

Thirty-two stars have been remarked at Toulouse, which are not in the Pulkowa catalogue; of these fifteen occur in Bond's catalogue, in vol. v. of "Annals of the Harvard Observatory"; the remaining seventeen which have not, as it appears, been previously observed, are generally very faint, the only notable exceptions being in the cases of two stars, which have the following estimated co-ordinates relative to θ^1.

$\Delta\alpha$	$+180''$	.. $\Delta\delta$	$-180''$
,, . ..	$110''$	. ,, ...	$480''$

The first star was 13 (an object termed *très belle* with the Toulouse instrument) on February 17, but had become extremely faint on March 14 and 26. The second star is estimated 13, almost as bright as its neighbour, No. 55 of Struve's catalogue. M. Tisserand states that he has not been able to recognise all the stars in Bond's catalogue, more particularly in the neighbourhood of the trapezium.

The numerous variable stars, which we have now reason to suppose exist in the nebula of Orion, certainly form one of the most significant and interesting features in the history of that grand object.

It may be added here that M. Tisserand has also employed the powerful optical means now at his command, upon observations of the satellites of Uranus.

NEW MINOR PLANETS.—Still another small planet is announced during the last week. It was found by M. Perrotin at Toulouse on April 26, in R.A. 14h. 11m. 48s, N.P.D. 96° 24′; twelfth magnitude.

The planet detected by Prof. Watson at Ann Arbor on April 19 is called No. 161 in the *Astronomische Nachrichten*. These numbers, however, are now in much confusion, and names for those which are observed a sufficient length of time to allow of the determination of elements have an obvious advantage over the system of leaving these planets to be distinguished by a number only. As regards numbers there is even doubt as far back as No. 149, which has not yet been shown to be distinct from Frigga (No. 77).

BIELA'S COMET AND THE NOVEMBER METEOR-STREAM.—If we take for the orbit of the November meteor-stream the elements calculated by Prof. J. C. Adams, and communicated to the Royal Astronomical Society in April, 1867, and for Biela's comet a mean of the sets of elements for the two nuclei in 1866, given by Clausen in "Melanges Mathématiques et Astronomiques," &c., t. iii., of the Imperial Academy of St. Petersburg, we find for the least distance between the tracks of the comet and the meteors, 0·054, the mean distance of the earth from the sun being taken as unity. This nearest point of approach is in heliocentric longitude 61° 30′ (equinox of 1866), where we have—

	Comet	Meteors.
Heliocentric latitude . .	0° 58′ N.	2° 57′ N.
True anomaly...	311° 44′	356° 24′
Radius-vector.	1·0266	0·9865

The approximation of the orbit of Biela's comet to that of the November meteor-stream, and consequently to that of Tempel's comet, 1866 (I.), was first pointed out by Prof. Bruhns, of Leipsic, in *Astron. Nach.*, No. 1681, but the heliocentrics there employed were deduced from the geocentric places of Santini's rough ephemeris.

PROF. FLOWER'S HUNTERIAN LECTURES ON THE RELATION OF EXTINCT TO EXISTING MAMMALIA[1]

IX.

THE disputed zoological position of the Lemurs, and the great importance which has been attached to them by some zoologists, who regard them as the direct transition between the lower and higher mammals, and as survivors of a large group now almost extinct, through which the higher Primates must have passed in the progress of their development, give great interest to the consideration of their ancient history.

Until very recently fossil Lemurs were quite unknown, at all events the affinities of certain remains provisionally assigned to the group were much questioned, but within the last few years the existence of Lemuroid animals in Europe during the early Tertiary period has been perfectly established, and remains of a large number of animals attributed, though with less certainty, to the order, have been found in beds of corresponding age in North America.

In 1872, a nearly complete skull of an animal somewhat allied to the modern African Pottos and Galagos, though of a more generalised character both of cranial conformation and dentition, was described by M. Delfortrie, under the name of *Palæolemur betillei*. It was found in phosphatic deposits, probably of early Miocene age, in the department of Lot. It was soon afterwards discovered that certain more or less fragmentary specimens which had been long before described, and had been generally though doubtfully referred to the *Ungulata*, were really nothing more than animals of the same group, and probably even of the same species. These are *Adapis parisiensis*, Cuvier, from the Paris gypsums, *Aphelotherium duvernoyi*, Gervais, and *Cænopithecus lemuroides*, Rutimeyer. The recognition of these animals as Lemuroids shows how little reliance can be placed upon the characters of the molar teeth alone in judging of affinities, and should also lead to the re-examination of some of the smaller mammals of our own Tertiaries, such as *Microlophus*, as it is not improbable that Lemurs may be found among them. The same deposits in which M. Delfortrie's specimen was found, have since yielded two other skulls, one of smaller and the other of larger size, named by M. Filhol, *Necrolemur antiquus* and *Adapis magnus* respectively. It should, however, be mentioned that M. Filhol only admits the first to be a true Lemur, and considers the genus *Adapis* as the type of a hitherto unknown group of mammals, intermediate between the Lemurs and Pachyderms, to which he gives the name of *Pachylemur*.

Of the supposed low and generalised forms of Primates from the Tertiaries of North America, the existence of which was announced almost simultaneously by Professors Marsh and Cope in 1872, it is difficult to speak with certainty at present, as the descriptions which have reached this country are not very detailed. As many as fifteen genera have already been named. They are nearly all from the Eocene formations, two only having been found in the lower Miocene.

The remains of no true monkeys have hitherto been discovered in the Eocene, but several species have been found both in Miocene and Pliocene formations in Europe. The most abundant and best preserved are those from Greece, *Mesopithecus pentelici*, allied to the existing genus *Semnopithecus*, though with shorter and stouter limbs. Others have been found in the Siwalik Hills of India allied to the same form, and in France, the South of Germany, and Italy, related to the Macaques and to the Gibbons. The most interesting species is one known by the lower jaw only, from a Miocene bed at St. Gaudens, in France, described by Lartet under the name of *Dryopithecus fontani*. Its affinities have given rise to some discussion, but as far as can be decided from the evidence before us, it appears intermediate between the chimpanzee and gorilla, and of the size of the former. Considering how nearly the Miocene fauna of Europe resembles in its general features the actual fauna of Africa, it is not surprising that an ape of the genus *Troglodytes* should have formed part of it. No remains of monkeys allied to the existing American forms have been found in the Old World, and conversely, all those discovered by Lund in the Brazilian caverns belong to the families now inhabiting the same part of the world. No monkeys have yet been found in the alluvial deposits of the plains, which are so rich in the great Edentates, nor in fact have they been met with in any older South American Tertiaries. The ancient history of the group, as revealed to us by palæontology, is therefore extremely incomplete. Further researches into the fauna of the North American Eocenes may throw some light upon it.

No actual remains of man have been met with which can be said with certainty to be older than the Pleistocene period, though it is asserted that his existence upon the earth in the Pliocene and even Miocene epoch is proved by works of art found in deposits of those ages. These, however, are questions to be decided by the antiquary and the geologist, and are beyond the scope of the anatomist. The oldest known remains of man from European caves (with perhaps the exception of the celebrated skeleton from the Neanderthal, the age of which is doubtful) do not differ more from modern Europeans than do several of the lowest modern races. In other words, no proof of the existence in former times of a race of men inferior in general organisation to the Australians, and forming any nearer approach to the lower animals, has yet been discovered.

In reviewing our present knowledge of the palæontology of the Mammalia we see immense progress of late years, giving hopes for the future. Here and there we have tolerably complete histories of gradual modification of forms with advancing time, and adapted to the exigencies of changing circumstances, as among the Ungulata and the Carnivora; and we have many instances of extinct forms filling the gaps between those now existing. But still there are great gaps or rather gulfs between most of the large groups or orders, without at present any trace of connecting links, or anything to indicate how they were once filled up, as must have been the case if they have all been gradually evolved from a common origin. We have very much to learn before we can speak with any confidence upon the manner in which all the diversities of form we see around us have been brought about, or attempt to construct pedigrees or phylogenies, except in the most provisional and tentative manner.

[1] Abstract of a course of lectures delivered at the Royal College of Surgeons "On the Relation of Extinct to Existing Mammalia, with Special Reference to the Derivative Hypothesis," in conclusion of the course of 1873. (See Report in NATURE for that year.) Continued from vol. xiii. p. 514.

INTERNATIONAL METEOROLOGY

THE Permanent Committee of the Vienna Meteorological Congress has just held its third meeting in London, which lasted from the 18th to the 22nd April inclusive. The members present were Prof. Buys Ballot (Holland), president, Professors Bruhns (Germany), Cantoni (Italy), Mohn (Norway), Wild (Russia), and Mr. Scott. Prof. Jelinek (Austria) was unfortunately absent owing to ill-health.

Among numerous subjects which came up for consideration, it appeared that the scheme for publication, in a uniform manner, of actual observations and monthly results from a limited number of stations in each country, which are to be considered as international, had been already accepted almost without exception or suggestion of amendment by all the countries which had been present at Vienna. It is hoped that this measure will ultimately tend to bring about uniformity in hours and methods of observation.

In weather telegraphy it was resolved to calculate gradients in the metric scale, as millimetres per one degree (sixty nautical miles). In this country they will be referred to English units. It was not found practicable to endeavour to introduce uniform hours for observations in weather telegraphy in Europe at present. As to weather charts, a proposal for the exclusion of all meridians except that of Greenwich was postponed to the next Congress. It was resolved to take advantage of that meeting to attempt to effect the comparison of the principal standard barometers by means of travelling barometers to be conveyed to the place of meeting, and left there for a considerable time.

It was recognised as impracticable at present to create an International Meteorological Institute, and consequently it was decided that international investigations must be carried on at the expense of individual nations, other nations to be requested to furnish materials, as far as possible, in a usable form. A list of upwards of 200 subscribers to the international synoptic weather charts of Capt. Hoffmeyer was announced.

Resolutions were adopted in favour of the establishment of stations on high mountains, and in distant localities, and Lieut. Weyprecht's proposition for a circle of observing stations in the Arctic Regions round the Pole was recognised as scientifically of high importance and deserving of general support.

With reference to universal instructions for observations it was stated that no general form of instructions could be drawn up to suit all climates, and it appeared to the committee that the instructions recently prepared in the German, Russian, and English languages respectively, as well as in Italian (as soon as some contemplated modifications shall have been introduced), were sufficiently in accordance with the requirements of the Vienna Congress. It was hoped that ere long French instructions of the same tenor would be issued.

It was announced that the Italian Government was prepared to invite the next Congress to meet at Rome in September 1877, and the proposal was most gratefully accepted. In preparation for this meeting a number of reports on the present state of the different departments of the science are called for from various meteorologists. The questions to be treated in these reports are mainly instrumental, and they are of great importance in the present state of the subject. The detailed Report of the Committee will be published without delay.

SOIRÉE OF THE ROYAL MICROSCOPICAL SOCIETY

ON Friday, April 21st, Mr. H. C. Sorby, president of the Royal Microscopical Society, gave a large *soirée* in the apartments of King's College. Invitations had been issued for above 1,500, including the whole of the Fellows of the Royal Microscopical Society, the presidents and leading officers of many of the London Scientific Societies; all the distinguished foreigners now in London as commissioners from the various foreign Governments to the Exhibition of Scientific Apparatus at South Kensington; and many of the President's private friends. About 800 were present, including about 300 ladies. After having been received by the President and one of the secretaries, the visitors passed into the various rooms of the College, in which were exhibited many objects connected with microscopical science. For the number, variety, scientific value, or general interest of the specimens, this exhibition has probably never been surpassed. Amongst the new instruments may be mentioned Mr. Sorby's arrangement for accurately measuring the wave-length of the centre of absorption-bands in spectra; a new form of Stephenson's erecting binocular microscope, by Mr. Bevington, and another by Mr. Browning, of somewhat different construction. Mr. Browning also exhibited his new portable microscope, which is so constructed that the body can be turned on one side and reversed in such a manner as to reduce the height to about one half. The President also exhibited a large series of specimens illustrating his own special subjects, shown by means of fifty microscopes, lent to him by four of the principal makers in London (Becks, Browning, Crouch, and Ross), and about 150 first-rate instruments and objects were contributed by the Fellows of the society and other friends. These were so distributed over the large apartments of the College as to avoid crowding in any part. Almost every branch of science to which the microscope has been applied was well represented, and many of the finest specimens ever prepared were shown and described. Many very interesting living objects were sent direct from the Brighton Aquarium and elsewhere. In the lecture theatre were exhibited Dr. Hudson's most beautiful drawings of microscopic objects shown in a new manner as transparencies; Mr. Spottiswoode's splendid polarising apparatus, and various objects shown with the oxy-hydrogen microscope by How and Company. The large entrance hall was decorated with plants and flowers, and used as a promenade. The two museums of the College were also thrown open. Refreshments were supplied by the steward of the College. The guests were provided with a classified catalogue of the objects exhibited, but they were so numerous that it was impossible for any one to examine more than a small part of the whole. One of the most satisfactory results of the *soirée* is the great impression produced by it on the foreign scientific men, who appear to have been quite unprepared for, and greatly surprised at, what they saw during the evening.

ON CERTAIN METHODS OF CHEMICAL RESEARCH [1]

THE lecturer began by describing the simple form of apparatus which he employed many years ago in his researches on the heat evolved in the combination of oxygen, chlorine, bromine, &c., with other bodies. In every case the bodies to be combined were inclosed in a vessel surrounded with water, and the combination was effected either by the ignition of a fine platinum wire, or where they acted directly upon one another, by the fracture of a glass capsule containing one of the combining bodies, the heat being measured by the rise of temperature of the water. He next referred to the arrangement by which he had been the first to decompose water so as to render visible the hydrogen and oxygen, and to measure their relative volumes by means of atmospheric electricity and of electrical currents from the ordinary machine. For this purpose fine platinum wires were hermetically sealed into fine thermometer tubes, which were then filled with dilute sulphuric acid by withdrawing the air by ebullition. The same current of frictional electricity will decompose the water in almost an indefinite number such couples arranged in a consecutive series. Capillary tubes of this kind may be employed for eudiometric experiments, which would be exceedingly tedious in wide tubes. Thus oxygen gas can at once be absorbed by passing the silent discharge through it while standing

1 Abstract of a Lecture to the Chemical Society by Dr. Andrews, F.R.S., April 28. Communicated by the author.

over a solution of iodide of potassium By means of the air pump it is easy with a gentle exhaustion to expand the gas so that it may fill the whole tube while the open end is immersed in the liquid which it is desired to introduce, on removing the pressure the gas will be in contact with the new liquid

The lecturer exhibited some of the original tubes with which Prof Tait and he first determined that ozone is a condensed form of oxygen, and explained a form of apparatus by means of which this important fact can be exhibited as a class experiment A full description of this apparatus will be found in his lecture on ozone, which was delivered some time ago before the Royal Society of Edinburgh, and has since been published by the Scottish Meteorological Society With this apparatus the lecturer has been able to determine that chlorine gas undergoes no change of volume from the prolonged action of the electrical discharge His experiments on this subject have not yet been published, but they were made under singularly favourable conditions for discovering a very small change of volume in the gas if any such change had occurred

The lecturer in the next place briefly alluded to the method he formerly employed for determining the latent heat of vapours of which a detailed account was given in a former communication to the Chemical Society The apparatus employed admits of exact experiments being made on a small scale, and consequently on substances in an absolutely pure state, an object of even greater importance in inquiries of this kind than in ordinary chemical analyses He remarked that a large field for investigation in this part of the domain of science lay comparatively uncultivated and would yield a rich harvest of results to anyone who would enter upon it

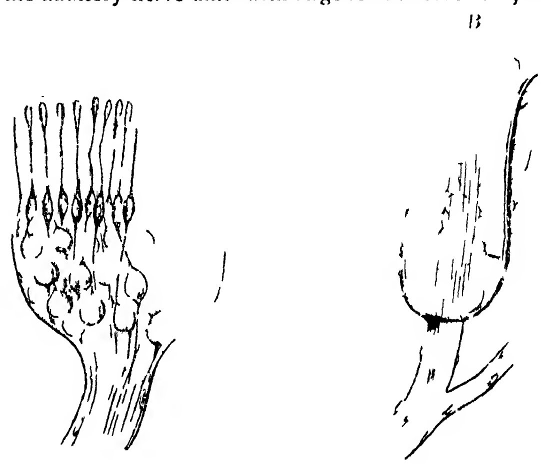
Passing from this subject the lecturer described a dividing and calibrating machine which he contrived some years ago for the special work in which he has been engaged, and which has given to many of his investigations an accuracy otherwise hardly attainable He has been enabled by means of it to construct thermometers whose readings are absolutely coincident throughout every part of the scale and to calibrate with almost perfect accuracy the glass tubes used in his pressure experiments It would be impossible in an abstract to describe the construction of this machine but it may be important to mention that the screw which moves the microscope or divider is a short one of remarkable accuracy constructed by Troughton and Simms

The last subject treated was the lecturer's method of investigating the properties of gaseous and liquid bodies at high pressures and under varied temperatures By means of his apparatus, which was exhibited to the meeting pressures of 500 atmospheres can be readily observed and measured in glass tubes in a word, a complete mastery obtained over matter under conditions hitherto beyond the reach of direct observations This has been effected by a novel mode of *packing* a fine steel screw, so that while entering a confined portion of water no leakage whatever occurs under enormous pressures, and also by a peculiar method of forming a tight junction between glass and metal The lecture was concluded by a short statement of the more important results lately communicated to the Royal Society on the properties of matter in the gaseous state

SCIENCE IN GERMANY

(From a German Correspondent)

IN my last communication (NATURE, vol xiii p 75), I noticed the researches of Ranke on various organs of sense of the lower animals A new series of these researches having since appeared, I will give some account of them in what follows Ranke (*Zeitschrift fur Wissenschaftliche Zoologie*, xxv, 2 Heft Supplement) has studied more closely, in their physiological relations the organ of hearing of certain grasshoppers (*Acridii*) and snails (*Pterotrachea*) and the eye of the leech, which organs were previously known in general from the researches of Siebold, Leuckart, Leydig, Boll, and others The Acridii carry their organ of hearing on the base of the hind most extremity It consists essentially of a membrane, which is stretched within the body wall on a fixed ring, and an auditory nerve, which is connected from within to that membrane, and ends on it in a swelling or so called ganglion That membrane is undoubtedly to be compared with the membrane of the tympanum in the ear of the most highly organised animals, inasmuch as, like this, it is put in vibrations corresponding to the sound waves in the air and transfers these vibrations to the parts lying within In the higher animals, these parts consist of rigid lever arrangements (small bones of the ear), which, however, are connected with the acoustic nerve not directly, but through a transmitting apparatus, which separates the vibrations produced by various sound waves and specially prepares them for conveyance by the nerve In the Acridii the whole internal conduction of the sound wave is more simply arranged, the ganglion on the tympanic membrane consists of two different halves in the interior the finest nerve threads proceeding from the auditory nerve unite with large round nerve cells, from



[illegible]

which they proceed to the boundary of the half of the ganglion and there end in smaller nerve cells The outer half of the ganglion consists of a brighter and delicate ground mass, in which very fine rods, transparent like glass, and fixed, run parallel towards the tympanic membrane they spring out of those smaller cells terminate on the tympanic membrane with longish thin ends and may be regarded as the end apparatus of the nerve conduction But while thus the vibrations of the tympanic membrane are communicated to the rods and from them direct, without further intervention, to the nerve apparatus there is not entirely wanting a weakening or damping arrangement for the sound wave for the ground mass, in which the rods rest may very well be regarded as such an arrangement As the rods are all formed alike, the sensations of tone by the Acridii must be always homogeneous and simple, and if we may suppose that the organ of hearing of these animals is adapted to their own production of tone, by which they excite sexual desire, then their monotonous rattle agrees with the arrangement of the auditory apparatus for a simple sensation In other grasshoppers, the Locustidæ, the vocal organ produces a sound compounded of more tones, and correspondingly, they have on their fore legs an organ of hearing, the rods in which are of various length and breadth, and, arranged like the wires in a

piano, evidently serve for excitation of different sensations of tone. The organ of hearing of the Acridia is then, simple, in a similar sense to that of the simple eyes which perceive light but not colours and forms, and therefore it closely approximates to the organs of touch, which likewise render sensible simple mechanical stimuli, and are often arranged in a way similar to those organs of hearing.

The eye of the leech consists of a cup-like inflexion of the skin, which is so lined with large transparent cells that only a narrow axial canal remains. The nerve stem which enters at the bottom of the cup, fills this canal up to a certain height and ends there with a ganglion, while the nerve fibres pass into small cells, whose outer end runs out into a short rod; the entire cup is coated round with a pigment skin and enveloped in muscles which are directed partly parallel, partly at right angles to the skin surface, and therefore can draw the whole cup with its sheath inwards or press the contents somewhat outwards. The former happens when the animal is surprised by sudden light, just as we close our eyes in like circumstances. After some time, the leech opens its eyes, a part of the glass-like cells on the rim of the open cup being pressed out in form of a compact hemisphere. In this way a pretty perfect visual apparatus is arranged. The outer glass-like hemisphere corresponds to the light-refracting medium of a more perfect eye. The mosaic of rod cells behind receives the separate rays and conveys the stimulus to the nerves, while the pigment layer cuts off all round the light that has penetrated. Besides these eyes on the upper lip the leech possesses on other parts of the body organs constructed quite similarly, only without a pigment skin, so that they cannot be visual organs. On the other hand they are thrust out when the animal is feeling about, and are thus evidently organs of touch; but at the same time the organs of sight are used in the same way, and when the animal sucks in the liquids agreeable to it it draws the upper lip with the open organs of sight into the mouth. It would appear, then, that these organs are at once the means of sensations of touch, taste, and sight. To conceive this rightly we must consider that in the lowest animals the special sensations of sense are not yet differentiated; their body is in all parts alike sensitive, and sensation can only mean, quite generally, ease or uneasiness. In a higher form of organisation, certain body parts are by peculiar arrangement, rendered sensitive to pressure, heat, light, and chemical stimulation. But before such a simple organ of sense develops in one direction for a particular kind of stimulus, it can also communicate simple sensations of a different kind. We ourselves know such a combination of different sensations through the same organ of sense; we [illegible] at the boundary of the tone-conductors, may feel, instead of tones, simply a vibration or a tickling, and thus has a sensation of touch like that produced in a finger-point when a vibrating tuning-fork is applied to it. Again, in our tongue, sensations of taste, smell, and touch are mixed together. Thus the organ of hearing of Acridia, which can only feel hissing noises, but no tones, may be compared, in the quality of its sensation to an organ of touch; and of the visual organ of the leech, it may perhaps be said that it receives somewhat of the sensation of touch and taste. In short, Ranke holds these organs to be of such a kind that the general feeling is not yet fully separated into the categories of touch, hearing, seeing, &c.

The ear of the Pterotrachea had long been known as a bladder, on whose inner wall are tufts of hair, the motions of which throw to and fro the otoliths or small spherical stones freely suspended within the bladder. It was believed that these continuous motions were connected with the sensation of hearing. Ranke proves, however, that they are merely due to convulsive movements of the animal in dying under the observation, and that the acoustical apparatus proper consists of a ganglion in the bladder wall, organised similarly to that in the Acridia. In the normal condition, the otoliths are pressed by the surrounding hair tufts against the acoustical apparatus only in the case of stronger sound stimuli, and they have then a damping action.

NOTES FROM THE "CHALLENGER"[1]

PROF. THOMSON in this paper after briefly referring to a visit to the Hawaiian crater of Kilauea, proceeds as follows:—

In the section between Hawaii and Tahiti, except at one station close to Tahiti, where the depth was 1,525 fathoms, the depth ranged throughout the section from 2,000 to 3,000 fathoms with a mean of about 2,600 fathoms, and the nature of the bottom was very uniform. Except in the neighbourhood of the groups of volcanic islands where it was found to be largely composed of volcanic [illegible] and shore mud, it consisted mainly of red clay, in many of the soundings containing a large admixture of the decaying shells of Foraminifera, and in almost all including a large proportion of manganese peroxide in the form of concretions from the size of a nut to that of an *Orlulina*[illegible] and passing into fine almost microscopic granules visible under a low power in every sample of sounding. In two patches the siliceous skeletons of Radiolarians were so abundant as almost to entitle the deposit to the name of Radiolarian ooze; and a patch between these, nearly halfway between Hawaii and Tahiti, in its abundance of surface Foraminifera approached to true "Globigerina ooze". The larger samples of bottom brought up in the dredge or trawl had therefore usually the same character as the contents of the [illegible] tube, and [illegible] the large manganese concretions up to the size of an orange or even [illegible], were collected in quantity, the greater part of the red clay being [illegible] out.

The surface temperature rose gradually in our passage southwards from Hawaii towards the equator, and again [illegible] from the equator to [illegible] Tahiti. The isothermals between 14° C. and 2° C. gathered together and approached much nearer to the surface in the region of the trade winds [illegible] to the equatorial belt [illegible] [illegible] [illegible] and the [illegible] direction of the wind. [illegible] the isotherm of the line of 14° C., which is at a depth of 90 fathoms a little to the north of Tahiti is at a depth of 100 fathoms on the line. In the Atlantic all the isothermals seem to [illegible] in the region of the trade winds [illegible] the lines below 14° C. [illegible] which extends from lat. 10° N. to lat. 10° S. [illegible] 5° C., which may be taken as a type of these [illegible] lines, is found in lat. 10° N. at a depth of 450 fathoms, and in lat. 10° S. at the same temperature within the limit of error of observation, while in lat. 2° 3' N. it is found at 675 fathoms. The point where the isothermals gather together most markedly and approach nearest to the surface is [illegible] the [illegible] of the [illegible] of the [illegible] counter current. This fall of temperature is so decided as to indicate some [illegible] of cold water, and it may possibly be due to some extent due to the [illegible] up of deeper and therefore colder layers of the colder [illegible] current [illegible] the [illegible] stream. In the equatorial region between lat. 10° N. and 10° S. there is a belt of water about 80 fathoms in thickness at a temperature generally over 25° C., and the whole of this water, with the exception of the narrow band of the counter current, is running to the westward at the rate of from forty to twenty miles a day.

The bottom fauna over the whole of the [illegible] area is very meagre both as to number of species and number of individuals.

After a week's stay at Tahiti the *Challenger* left the harbour of Papeete on the 3rd of October and arrived at Valparaiso on the 19th.

[1] Preliminary Report to the Hydrographer to the Admiralty on some of the Results of the Cruise of H.M.S. *Challenger* between Hawaii and Valparaiso. By Prof. Wyville Thomson, F.R.S., Director of the Civilian Scientific Staff. Communicated by the Royal Society.

[illegible] The words *[illegible]* [illegible] are here used to [illegible] lines of equal temperature [illegible] of the earth [illegible] [illegible] the [illegible] *[illegible]* are [illegible] the [illegible] [illegible] drawn through points of equal temperature in a vertical section, and the latter, lines drawn through points of equal depth at which a given temperature occur. Isothermolaths are shown in a scheme of a vertical section such as Plate II. Isobathytherms are of course projected on the surface of the globe.

The section from Papeete to Valparaiso (Plate III) is about 5,000 miles in length, and is naturally divided into two parts, the run southwards to the parallel of 40° S., and the course along that parallel towards Valparaiso.

Setting aside Station 279 in 680 fathoms close to Tahiti, the mean depth throughout the section was 2,139 fathoms, considerably less than that of the meridional section from Honolulu to Tahiti, and very much less than that of the section in the North Pacific, between Japan and San Francisco. The nature of the bottom is very much the same as in the meridional section, red clay imbedding nodules, and lumps of various sizes of manganese peroxide, and passing in the shallower soundings into more or less pure Globigerina ooze, and as in the section between Hawaii and Tahiti the fauna is generally meagre. The trawling between Juan Fernandez and Valparaiso (Station 298) was particularly interesting, animal forms were much more abundant than they usually are in the Pacific, and the general character of the assemblage resembled in a remarkable degree that of the fauna of the Southern Sea in the neighbourhood of the Crozets and Kerguelen, many of the species, including some singular Urchin of the family Ananchytidæ, being identical. The bottom at this station was a bluish mud, the surface layer containing little or no carbonate of lime, and curiously enough a deeper layer, with a considerable proportion of Globigerina shells. There was no considerable quantity of manganese in the sounding. Notwithstanding the considerable depth of 2,225 fathoms, the conditions in this locality seem much more favourable to animal life than even the manganese area, and I am inclined to think that we had struck upon one of the highways by which migration takes place to the northward from the Southern Sea.

Although there are certain points which have yet to be worked out in detail, the general distribution of temperature in the Pacific seems sufficiently simple. In the first place, the whole mass of water consists of two well marked divisions, an upper layer of no great depth, in which there is rapid cooling from the surface downwards, and considerable variation in temperature in different localities; and a mass of water of incomparably greater amount, which extends to the bottom, and which may be said to have nearly the same temperature throughout. These two divisions shade into one another, but the isothermobath of 5° C. may be taken as indicating generally the limit between them, below this line the isothermobaths are still affected by surface thermal conditions, but comparatively slightly. Above the line of 5° C. the course of the isothermobaths is to all appearance entirely regulated by causes affecting the surface temperature, that is to say directly or indirectly by surface currents produced by permanent, periodic, or variable winds. The equatorial current occupies the region of the trade winds, approximately from lat. 20° N. to 20° S., and there is a strong but narrow counter current entirely comparable with the counter current in the Atlantic between the parallels of 5° and 8° N. The water of the equatorial current has no free egress to the westward, being intercepted by the peninsula of Malacca and the islands of the Malay archipelago, but neither is it completely arrested, as the equatorial current is in the Atlantic by the unbroken coast of America, consequently a return current less permanent and less defined than the return current in the Atlantic finds its way to the north-eastward along the coast of Japan. The course of the Japan current is much the same as that of the Gulf-stream, and is due, as in the Atlantic return current, to the high initial velocity of the intercepted water, its influence on the temperature of the ocean is, however, much sooner reduced and obliterated.

The hot water of the Pacific equatorial current, instead of being gathered together and focussed by the form of the land-barrier, as it is in that of the Atlantic, spreads out in the middle and West Pacific in a vast sheet of abnormally warm water, extending to a depth of nearly 100 fathoms, thus the isobathytherm of 25° C. at 80 fathoms passes near Hawaii and Tahiti, and near the parallel of 20° N. on sections between the Admiralty Islands and Japan. The lower isothermobaths of the upper layer are a little nearer the surface in lat. 40° N. than in lat. 40° S.; and this I believe to be due to the banking of the Antarctic indraught against the Arctic land-barrier, and to be the only case in which the position of the lines of equal temperature in the upper layer is not absolutely dependent upon the wind.

The temperature of the underlying cold water is derived from another source, and its distribution is governed by other laws. Throughout the Pacific the isothermobath of 5° C. maintains on the whole a very even course, oscillating between the 400 and 500 fathom lines. These oscillations depend upon causes acting on the surface, for the line rises and falls in harmony with the higher isothermobaths. The line of 5° C. deviates sensibly on two occasions from its comparatively straight course. In the equatorial region it sinks to a depth of 625 fathoms, probably from the communication of heat from the upper layer of water by mixing; and in lat. 40° it rises to 300 fathoms, probably, as I have already said, from the accumulation of cold water against the Arctic barrier. The next three degrees of temperature are lost with increasing slowness in the next 700 fathoms, the line of 2° C. making a very even course at a depth of 1,100 fathoms, and the remaining degree or degrees and a fraction being lost between 1,100 fathoms and the bottom. The depth of the Pacific increases slowly from the south to the north, the mean difference between the depth of the South Pacific and that of the north being perhaps as much as 1,000 fathoms. Notwithstanding this increase in depth, we have satisfied ourselves, although the determination is one of great difficulty, that the bottom temperature rises slightly from the south northwards. We can scarcely say more than that it rises slightly, for the differences in the temperatures below 1,500 fathoms are so small that a result can only be arrived at by a careful combination and comparison of many observations, taking into full consideration the errors of the thermometers arising from all sources. There is a like very slight decrease in the bottom temperatures from east to west.

I think we can scarcely doubt that like the similar mass of cold bottom water in the Atlantic, the bottom water of the Pacific is an extremely slow indraught from the Southern Sea. That it is moving, and moving from a cold source, is evident from the fact that it is much colder than the mean winter temperature of the area which it occupies, and colder than the mean winter temperature of the crust of the earth; that it is moving in one mass from the southward is shown by the uniformity of its conditions, by the gradual rise of the bottom temperatures to the northward, and by the fact that there is no adequate northern source of such a body of water, Behring's Strait being only forty fathoms deep, and a considerable part of that area being occupied by a warm current from the Pacific into the Arctic Sea, and by our knowledge from observations that one or two trifling currents from the Sea of Okotsk and the Behring Sea, which are readily detected and localised, and are quite independent of the main mass of cold water, represent the only Arctic influx. During its progress northwards the upper portion of the mass becomes slightly raised in temperature by mixing with, and possibly by slow conduction from, the upper layers which are affected by solar heat. At the end of the Gulf, that is to say in the extreme north, furthest from the cold source, the temperature is, as I have already pointed out, influenced to the very bottom, and the isothermobaths between 8° and 5° C. are obviously raised and pressed together, probably by the accumulation of the cold water against the land. The colder bottom water to the westward might be expected from the lower initial velocity of the Antarctic water causing it to drag against the west coast.

I am every day more fully satisfied that this influx of cold water into the Pacific and Atlantic oceans from the southward is to be referred to the simplest and most obvious of all causes, the excess of evaporation over precipitation in the northern portion of the land hemisphere, and the excess of precipitation over evaporation in the middle and southern part of the water-hemisphere.

After what I have already said I need scarcely add that I have never seen, whether in the Atlantic, the Southern Sea, or the Pacific, the slightest ground for supposing that such a thing exists as a general vertical circulation of the water of the ocean depending upon differences of specific gravity.

NOTES

The forty-seventh anniversary of the Zoological Society was held on Saturday last, Viscount Walden, F.R.S., the President, being in the chair. Mr. P. L. Sclater, F.R.S., the Secretary, read the report, which showed that the income (28,757) was greater than it had been in any previous year since the foundation of the Society. The total number of visitors in 1875 had been 699,918. The new lion house had been, as far as its main portions were concerned, completed and opened to the public. The building contains fourteen dens, the

larger of which measure 20 ft. by 12 ft., the smaller being 12 ft. square. The out-door cages are to be completed by the end of July next; they will measure 44 ft. by 29 ft. Mr. Sclater desired it to be known that of the larger Felidæ, the Ounce (*Felis uncia*) was a desideratum. The adoption of the report was moved by Prof. Huxley, seconded by Prof. Tennant, and carried unanimously.

OUR readers will regret the very sudden death of Lieut. J. E. Cornelissen, which occurred at Brussels in the month of March. Those who enjoyed the pleasure of his acquaintance will remember the hearty sailor-like demeanour of the man, while all who have paid attention to maritime meteorology will be ready to recognise his high scientific merits and the practical turn of mind which made the marine publications of the Utrecht Institute so eminently useful to seamen. He had been for sixteen years at the head of the marine branch of that establishment, having succeeded Andrau. He leaves a wife and four children utterly unprovided for.

THE following are the names of the Commissioners appointed to inquire into various matters connected with the Scottish University:—Lord Justice-General Inglis, the Duke of Buccleuch, Lord Moncreiff, the Right Hon. Lyon Playfair, C.B., Sir William Stirling Maxwell, James Craufurd, one of the Senators of the College of Justice in Scotland, William Watson, her Majesty's Solicitor-General for Scotland, John Muir, D.C.L., James Anthony Froude, Archibald Campbell Swinton, LL.D., Prof. Huxley, Dr. James Alexander Campbell, LL.D.

WE learn from the *Illustrated Australian News*, of Feb. 23, that a party consisting of Mr. Lawes, M. O. C. Stone, F.R.G.S., Mr. Hargreave, of Sidney, and Mr. K. Broadbent, bird collector, together with several Southsea Islanders, have made a successful excursion into the interior of New Guinea from Port Moresby. They attained a village called Munikaihila, situated 1,000 feet above the sea-level, and were well received by the natives. The view from this point was very fine. "All around were mountains and hills of every shape and size, covered with trees to the very summits," and Mount Owen Stanley rose as a grand background to the panorama apparently about twenty miles distant. We shall no doubt shortly receive a notice of Mr. Broadbent's discoveries.

WE have much pleasure in noting that in the monthly publication of tri-daily meteorological observations issued from Vienna, Dr. Jelinek has this year included two stations the observations at which, in addition to their climatological importance, cannot fail to be of the greatest value in constructing weather-maps, viz., Sulina, near the mouth of the Danube, and Alexandria, in Egypt.

IN a further discussion of the temperature observations made at the Museum of Natural History, at Paris, the MM. Becquerel point out that the mean temperature of the soil under grass is a little in excess of that under bare soil, and that under grass the temperature has not fallen below 32°, a fact of some importance in horticulture.

PROF. NORDENSKJOLD is to leave Gothenburg, on July 10, in a steamer of 163 tons for another cruise to the mouth of the Jenesei. He will sail up the river as far as Dudinko, when the steamer will take merchandise on board and return to Norway, the object of this expedition being to prove that there is a maritime route between Norway and the Siberian coast. We learn from *L'Explorateur*, moreover, that a Russian steamer is to leave the Jenesei and proceed to St. Petersburg by the Kara Sea, the North Sea, and the Baltic.

M. MARIE DAVY, the Director of the Montsouris Observatory, is to try whether Crookes's rotating radiometer can be utilised for actinometric purposes. No establishment is in a better position to try the experiment, Montsouris being supplied with regular actinometers, and special tables having been calculated for regulating as far as possible, their daily use.

IT is announced that Sir Bartle Frere is to be made a baronet.

THE Queen has conferred upon Lieut. Cameron—who was presented to her Majesty last Friday—the honour of Companion of the Bath, in recognition of his distinguished services in Africa.

AT the Annual Meeting of the Royal Institution on Monday, a piece of plate and a purse containing 300 guineas, were presented to Prof. Tyndall as a testimonial of congratulation on his recent marriage.

DURING the siege of Paris experiments were tried to make use of the conductibility of the Seine in order to establish communications with the outer world in spite of the Prussian blockade. Paris, however, surrendered before the apparatus had been arranged on the Upper Seine. This scheme has not been totally abandoned, and M. Bourbouge a *preparateur* of the Sorbonne has tried to establish the telegraph without wire. According to M. Parville, the plan has succeeded at a small distance by expending a large quantity of electricity, not less than forty elements being required to work a magnetic needle at a distance of a quarter of a mile. The same experimenter is said to collect spontaneous currents from the earth with large electrodes. The interest of these experiments is unquestionable.

FROM the "Annual Report upon the Survey of Northern and North-western Lakes, in charge of C. B. Comstock, Brigadier-General, U.S.A.," we learn that the triangulation has been carried around the south end of Lake Michigan, and stations have been located for its extension south and east toward Lake Erie. On Lake Ontario the topography has been essentially completed from the head of the Saint Lawrence along the south shore to within twenty miles of the Niagara River, and the off-shore hydrography has made about the same progress. Triangulation-stations have been located as far west as Erie, Pa. and have been built as far as the Niagara River. Charts of Lake Saint Clair, and No. 2 of the Saint Lawrence River are completed. It is proposed during the present fiscal year to complete the field-work of the survey of Lake Ontario and commence that of Lake Erie In the estimate of $184,000 for the survey of the lakes for the next fiscal year, an item of $25,000 has been included for the survey of the Mississippi River. No complete and accurate survey of the river has ever been made.

PART I., No IV., for 1875, of the *Journal of the Asiatic Society of Bengal*, contains papers on the Angámi Nágas and their language, by Capt. J. Butler, on the Maiwár Bhils, by Mr. T. H. Hendley, and specimens of popular songs of the Hamirpur District, Bundelkund, by Mr. F. A. Smith.

THE fifth part of the Bulletin of the Bussey Institution of Harvard University for 1876, completing vol. i., has just been published, and contains a number of valuable papers, principally by Prof. Storer, Dr. Farlow, and Mr. Sargent. Dr. Farlow's papers treat of the fungi found in the vicinity of Boston, of the olive and orange trees of California, of the American grape-vine mildew, and of the black knot. Mr. Sargent reports the addition of 165 species of trees and shrubs to the arboretum during the past year, and that over 100,000 plants have been raised. The papers of Prof. Storer, as usual, are of much scientific value.

ON the 10th of January last, Mr. Lancelot Studdert, LL.D., read a paper before the Royal Irish Academy (since published in the *Proceedings* of that learned body) on "The free and

albuminoid ammonia yielded by the stagnant waters of the Dublin streets, as compared with the quantities of those substances obtained from the Liffey water receiving the sewage." Twenty-nine street waters were examined; the mud, also, left from some was examined for ammonia. The following are Dr. Studdert's deductions:—The average of free ammonia from the four samples of the river was 0·0982, or under 1-10 of a grain in the gallon; the average of albuminoid ammonia from the same is 0·0779, or under 1-12 of a grain in the gallon. The average of free ammonia obtained from the twenty-nine street waters is seventeen grains to the gallon, that is, over 170 times the like average from the river. The average of albuminoid ammonia from the street water is three grains to the gallon, or thirty-eight times the Liffey average. The maximum of free ammonia from the river only reached 0·175, or less than 1-5 of a grain to the gallon, whilst the maximum of free ammonia from the street waters was 105 grains to the gallon, that is exactly 600 times greater than the river maximum. The least impure of the twenty-nine street waters yielded nearly three times more albuminoid ammonia than the most impure sample of the river water. The average of disintegrating animal refuse in the Liffey is 0·779, or just 3-4 of a grain in the gallon, whilst the average of such refuse in the street waters is twenty-nine grains to the gallon. That much of this animal matter must, if not rapidly removed, take forms that will vaporise, seems to the writer all but certain, since the conditions for spontaneous decomposition may be said to be always present; and he concludes that the continued presence of so much dirt in the streets would go far to account for the high death rate (33 to the 1,000, yearly), then lately recorded for Dublin, and that better scavenging and a level surface for the streets are at once required.

THE proposal for establishing a mountain exploration club in America, with similar objects to the Alpine clubs of England and Switzerland, is meeting with a good deal of encouragement, and several meetings have been held for the purpose of organising it.

MR. BRYCE M. WRIGHT, of No. [illegible] Great Russell Street, Bloomsbury, has just received [illegible] a perfect specimen of fossil Turtle (*Chelone hoffmanni*) from the Upper Chalk of Maestricht. It is 4 feet 1 inch in length and [illegible] inches wide, more than twice as large as the largest English specimens from Harwich and Swanage, Dorset, and is indeed the largest known.

THE correspondent J. C. who last year sent us a query concerning the cause of death of the house fly, writes that recently he noticed that a humble bee had five small animals like yellow spiders on its neck, and two more on its body. He had previously noticed a number of hive bees lying dead on the greenhouse floor. Another correspondent explained that the death of the fly was caused by parasites, and J. C. wishes to know if those on the bee are the same, and if they cause the death of bees as well as flies.

THE Lord Mayor and the Lady Mayoress will entertain the President of the Royal Society, the Astronomer Royal, the Presidents of the Royal Colleges of Physicians and Surgeons, and other distinguished representatives of science, at a grand banquet in the Mansion House, on Saturday-week, the 13th instant.

THE opening meeting of the Northamptonshire Natural History Society and Field Club was held at Northampton on April 21, Lord Lilford in the chair. This Society starts under good auspices, with a roll of sixty members, and we hope it will soon get into vigorous working trim.

IT is officially announced that the Philadelphia Exhibition will be opened on the 10th instant.

THE additions to the Zoological Society's Gardens during the past week include two Bennett's Cassowaries (*Casuarius bennetti*) from New Britain, presented by the Rev. George Brown; an Indian Gazelle (*Gazella bennettii*) from India, presented by Lieut. King, 76th Regiment; a Common Badger (*Meles taxus*) European, presented by Mr. W. P[illegible]; a Dusky Ichneumon (*Herpestes pulverulentus*) from India, a Narrow-fronted Crocodile (*Crocodilus frontatus*) from W. Africa, presented by Dr. Alex. Jennens; four Black-headed Sternotheres (*Sternothaerus subniger*) from Madagascar, presented by Mr. Lionel Hart; two Protei (*Proteus anguinus*) European, presented by Sir [illegible]; a White-fronted Capuchin (*Cebus albifrons*) from S. America; a White-throated Capuchin (*Cebus hypoleucus*) from Central America, a Lyre Bird (*Menura superba*) from Australia, a Hoffmann's Sloth (*Choloepus hoffmanni*) from Panama, three Common Boas (*Boa constrictor*) from S. America, deposited; a Collared Fruit Bat (*Cynonycteris collaris*) born in the Gardens.

SCIENTIFIC SERIALS

Journal of the Chemical Society, No. clix., March 1876.—This number contains a lengthy account of the researches of Dr. Wright and Mr. G. H. Beckett on narcotine, cotarnine, and hydrocotarnine, being the third of a series of papers read by them before the Chemical Society on their researches in this direction. Mr. E. Neison gives an account of the sebates of the alcoholic series and an additional note on the sebate of cobalt.—A paper by Mr. J. J. [illegible], B.Sc., on some compounds of ether with anhydrous metallic chlorides, and one by Mr. R. W. Emerson MacIvor, on the iodides of antimony, complete the list of those papers read before the Chemical Society.—Numerous abstracts of papers published in other journals on various branches in the different departments of chemistry occupy the greater part of the work now before us.

Gazzetta Chimica Italiana, Fascicolo IX. e X., Anno V., 1875.—These parts contain the following papers:—Action of anhydrous chloral, and of the hydrate, on aniline, by D. Amato. The author has obtained by this reaction a new base formed according to the equation

$$CCl_3COH + 2C_6H_5NH_2 = H_2O + CCl_3CH\begin{cases}NHC_6H_5\\NHC_6H_5\end{cases}$$

Chloral. Aniline. New base.

The new substance forms [illegible] tabular crystals melting at [illegible], soluble in alcohol, ether, and benzene, and insoluble in water. Distilled with excess of potash it yields phenyl-cyanide:

$$CCl_3CH\begin{cases}NHC_6H_5\\NHC_6H_5\end{cases} + 5KHO = 3H_2O + 3KCl + 2C_6H_5CN$$

The author describes also the hydrochloride $CCl_3CH(NHC_6H_5)_2HCl$, and the platino-chloride $[CCl_3CH(NHC_6H_5)_2HCl]_2PtCl_4$.—Study of essence of Cubebs, by A. Oglialoro. The author shows that this substance contains: (1) a small quantity of a hydrocarbon $C_{10}H_{16}$, boiling at 158–163°; (2) A hydrocarbon $C_{15}H_{24}$, boiling at 264–265°, forming with hydrochloric acid the compound $C_{15}H_{24}2HCl$; (3) A hydrocarbon boiling at 262–263° not forming a compound with HCl, the composition of which is at present doubtful. The action of these hydrocarbons on the polarised ray is also described.—On the natural poison of the extract of human bodies, by Prof. A. Moriggia and A. Battistini. The remainder of the part is occupied by extracts from foreign journals.

Poggendorff's Annalen der Physik und Chemie, Ergänzung Band vii. Stück 3.—In a paper in this number on the magnetism of steel bars, by M. Fromme, it is shown that the temporary magnetism increases at first more slowly, then more quickly, and again more slowly than the magnetising force. M. Fromme also got the interesting result that when the remanent magnetism, through repeated action of a force P, has reached its limit, (the saturation corresponding to this force) a smaller force p, is not capable of altering it. For every permanent magnetisation of a steel bar there are, from zero onwards, a series of magnetising forces, in relation to which the bar has the properties of a bar of soft iron (without coercive force). Exact determinations were made of the function of magnetisation for forces having this effect; and it is shown that the Neumann-Kirchhoff developments on this subject cease to hold good as soon as the steel is permanently magnetic. M. Fromme further finds that the temporary magnetism of a steel bar with repeated magnetisation by a constant current, decreases, but in such a way that the whole magnetism

remains unchanged; thus, what is gained in remanent magnetism is lost in temporary.—Dr. Dibbit observes that ammonium-sulphate, ammonium-oxalate, and ammonium-acetate, in boiling solution, are partly decomposed, on addition of equivalent quantities of the chloride or the nitrate of potassium, sodium, or barium; that decomposition is greater, the greater the quantity of chloride or nitrate added; and that in all cases the solution contains, at 100°, four salts. From other experiments he infers that the presence of salts in ammonia solution increases the quantity of evaporated ammonia in relation to the evaporated water (even where the salts are such as enter into known combinations with ammonia), and this both at the ordinary and at the boiling temperature.—M. Holtz calls attention to the polar electric attraction of fine particles suspended in liquids when under the influence of electric currents. There is always, along with the movements of translations, an attachment to one pole or the other; very well seen with lycopodium powder in sulphuric ether. Some substances seem indifferent, neither wandering nor clinging to the poles, but if the bottom of the vessel be clean and free from air moisture, they form into beautiful, regular, characteristic figures. These may be had, *e.g.*, with finely-powdered manganese, or iron oxide, or sawdust, in petroleum, oil of turpentine, benzine, or sulphuric ether. The figures are rarely long stable; they show various internal movements, not essentially altering the character of the figure; and there is sometimes rotation.—M. Sohncke advances a new theory of crystalline structure, based on unlimited regular point systems; and Dr. Exner gives an account of his recent researches on galvanic expansion of metallic wires; which are noticed elsewhere in our columns.

Zeitschrift der Oesterreichischen Gesellschaft für Meteorologie, Jan. 15.—Dr. Mohn contributes an article to this number on the causes of the greater depressions of the barometer in winter than in summer. His present views on this subject are different from those given in his work on meteorology. He explains that in order that a barometric minimum may attain a great depth, the ascending current must develop itself with ease and rapidity. Therefore, besides high temperature and a large amount of vapour, the air supplying the ascending current must possess qualities unlike those of the surrounding atmospheric region, so that the ascended air may flow off easily at great heights. The easier barometric maxima can be formed, the easier the development of minima. In winter the strong continuous radiation over the Continent tends to create maxima; the cooling of the air over the sea is moderated by the quantity of vapour always present and by the ocean temperature, so that minima are formed. In summer opposite conditions prevail, but no nightly radiation comparable to that of the land in winter can occur, and thus only small depressions are observed. In a similar way the low pressure of the antarctic zone between lat. 70° and lat. 75° may be understood to be caused by the position of this region between two districts with high pressure, the one northwards about the tropic of Capricorn, the other the great Frozen Antarctic Continent. Between these two maxima lies an unbroken sea developing conditions favourable to the existence of minima.—The next paper is by Dr. G. Hellmann, on the daily period of rainfall at Zechen.

Journal de Physique, January.—The substances used in thermometers are generally such as are not in the neighbourhood of their change of state; but (as M. Duclaux here shows) by using liquids that are near critical periods, very sensitive instruments may be had. Thus, if we mix 10 c.c. of crystallisable acetic acid with 5, 10, 15 c.c. of benzine at about 20° we have, in each case, a homogeneous mixture; and in cooling the three liquids we come, with each, to a point at which it is troubled, and at length divides into two layers. The upper layer is found nearly always to contain one-third of acetic acid for two-thirds of benzine; while the lower contains two-thirds of acetic acid and one-third of benzine. There are few combinations of *two* liquids that show small variations so distinctly as this one (acetic acid and petroleum is another). But a good mixture may be had by taking 10 c.c. of amylic alcohol, 25 c.c. of alcohol at 50°, and adding enough water to produce a slight opalescence. The least fall of temperature divides the mixture into two layers of nearly equal volume. Such a mixture will serve to show, *e.g.*, the cold produced by solution of marine salt in water. By varying the quantity of water the mixture may be so made as to become troubled at any temperature desired; and so a series of minimum thermometers may be constructed. A little carmine may be used to make the changes more apparent.—M. Deprez, in this number, gives some useful directions on the construction of electro-magnetic registers; and M. Branly describes the electrometer he uses for measuring electromotive force, resistance, and polarisation.

SOCIETIES AND ACADEMIES

London

Chemical Society, April 28.—Prof. Andrews, F.R.S., delivered a most interesting lecture on certain methods of chemical research (see p. 12).

Anthropological Institute, April 25.—Col. A. Lane-Fox, president, in the chair.—Dr. Comrie, R.N., exhibited his collection of weapons and articles of domestic use from New Guinea, and added several particulars to his previous remarks.—Mr. A. Tylor, F.G.S., read a paper on the origin of numerals. He held that inventive thought had always an object origin, and mentioned measures of length, as pace, foot, hand, &c., as having such a source. Also in the Ptolemaic hieroglyphics, a minute or second was shown by an eye-winking, answering to "the twinkling of an eye." Illustrations of the Abacus and mode of calculating by it were exhibited, and shown to be in principle the origin of the modern calculating machine. The dream of a universal language has been realised, as far as numerals and arithmetical figures are concerned, and this is due to their origin.—A paper by Mr. A. L. Lewis was read on some apparent coincidences of custom and belief in Chaldæa and other countries. He alluded, amongst other points, to the marks of finger-nails upon the terra-cotta deeds that had been discovered at Nineveh. They appeared to him to answer to the practice of touching the seals of legal documents with the finger. As regards the belief of the Assyrians in immortality, souls were either united with the sun, or descended to "Bit-Edie." Annwn, the country of the dead, in like manner amongst the Kymry was situated in the lower regions, at the going down of the sun in the west. The children of Anu, or the Sky, in Assyria, may be compared with "Cum Annwn," spirits, believed in by the Kymry. Amongst the Assyrian gods, Hed answered to the Lycian deity "Hu." Civilisation appeared to originate with the Turanians, the Semitic race merely succeeding to it.—The President, Mr. A. Smee, Mr. Distant, and others, took part in the discussion.

Physical Society, April 29.—Prof. Gladstone, vice-president, in the chair. The following gentlemen were elected members of the Society: Prof. F. Fuller and Capt. L. H. White.—The Secretary read a communication from Sir John Conroy, Bart., on a simple form of heliostat. The defect of Fahrenheit's heliostat, in which the beam of sunlight is deflected by a mirror moved by clock-work in a direction parallel to the axis of the earth, and then in the required direction by a fixed mirror, consists in the great loss of light. The author substitutes two silvered mirrors for the looking-glasses usually employed, and he has shown that the loss of light with this arrangement is less than when the light is once reflected from a looking-glass.—Mr. S. P. Thompson then made a second communication on the so-called "Etheric Force," and described some experiments which he has recently made in the Physical Laboratory at South Kensington on the subject. The name was given by Mr. Edison, the inventor of the motograph, to the sparks obtained when a conductor is presented to the core of an electro-magnet, the coils of which are traversed by an intermittent current. The results of the experiments conducted as originally described not proving satisfactory, various other arrangements were tried, and it was found that if the secondary current from an induction coil be used, instead of a current direct from the battery, the effects are much more marked. When the induced spark was diverted either wholly or partially into a short coil which was insulated very perfectly from the core inside, a spark about half an inch in length, which had a decided effect on the nerves could be drawn off from the core, and this was sufficient to illuminate a small vacuum tube; the spark, however, does not exhibit the usual signs of polarity. It was shown by observing the illumination thus produced with a rotating mirror, that the discharge is in reality a reciprocating one, each spark returning on its path after a minute interval of time. Under certain conditions it is also possible to charge an electroscope either positively or negatively by means of the spark, and Mr. Thompson has shown that the spark ignites a jet of gas but fails to deflagrate metallic wire or ignite gunpowder. From the above, and other

THURSDAY, MAY 11, 1876

THE LOAN COLLECTION

THE Queen will on Saturday open to the public the magnificent collection of scientific instruments, the arrangement of which has for several months been tasking the energies of the Science and Art Department and of the eminent men of science who have generously volunteered their assistance. This event may justly be regarded as an "epoch-making" stage in the progress of science, not only in this country, but in the world at large; for, as our readers know, the collection is essentially an international one, the principal nations of the world having vied with each other in contributing to render it worthily representative of the present state of science, and of the progress of its methods from the time when man first began feebly to question Nature. England may well be proud that the idea of such a collection originated with the English Science Department, and that the first international scientific loan collection will be exhibited in her capital. It may be that this collection will not attract such a crowd of visitors as would flock to gaze on an exhibition of pictures, or musical instruments, or embroidery, or old china; but, if the British public still retains its normal amount of curiosity, surely the magnitude of the present collection, the historical interest attaching to many of the objects exhibited, the number and eminence of the contributors, and the fact that the principal governments of Europe have enthusiastically seconded the efforts of the British Government, ought to excite that curiosity to the utmost. A great deal of mystery still hangs about science and scientific men and scientific methods in the eyes of many; here then at last have people an opportunity of inspecting for themselves these mysterious instruments by means of which men of science have reached those results that are stirring the minds of all thoughtful men, and have revolutionised ideas and methods in all departments of human activity. Englishmen must be duller and more incurious than we take them to be, if they do not show a fair amount of interest in that scientific collection which her Majesty will open on Saturday.

But while many, no doubt, will be attracted to the galleries of the International Collection by mere curiosity, we are sure that the scientific education of this country is sufficiently advanced to secure a large proportion of visitors animated by an intelligent and educated eagerness to gratify their scientific tastes by inspecting apparatus the importance and uses of which they are well enough taught to appreciate. Both to this latter class and to those who still lie in unscientific darkness, the two thick volumes [1] which have been issued—prepared at the request of the Lords of the Committee of Council on Education—as guides to the Loan Collection ought to be a welcome boon. Some idea of the extent of the collection may be obtained from the fact that these two volumes together number nearly 1,000 pages, and they are both at present incomplete. With these in his hands as guides no visitor need go empty away from the collection. A careful perusal of these two volumes combined with a systematic series of visits to the various sections of the collection, would, like the acquaintance of a certain noble lady, be in itself a liberal education; and indeed few better methods could be devised of rousing a love for science in the minds of intelligent people.

In two previous articles we have attempted to give a general sketch of the nature of the collection; in the present article we shall, with the two volumes referred to as guides, briefly give some idea of its extent and arrangement. The large Committee—and there is scarcely a scientific name of eminence absent from it—that met little more than a year ago at the request of the Lords of the Committee of Council on Education to confer on the organisation of a Loan Collection of Scientific Apparatus ought to be proud of the results of that first conference as embodied in these two valuable publications. The names on this Committee, and those on the Committees formed in foreign countries, number somewhere about 300; a glance at the lists shows that the names are those of the foremost scientific workers of our time. Specially gratifying must the result be to the staff of volunteers who have assisted in the arrangement of the collection, and whose names their Lordships justly record with "great satisfaction." They are: Capt. Abney, Dr. Atkinson, Mr. Bartlett, Dr. Brunton, Dr. Biedermann, Prof. Crum-Brown, Capt. Fellowes, Prof. Carey-Foster, Dr. Michael Foster, Herr Kirchner, Prof. Goodeve, Dr. Guthrie, Commander J. A. Hull, Mr. Iselin, Mr. Judd, Mr. Norman Lockyer, Dr. R. J. Mann, Mr. Clements Markham, Prof. H. MacLeod, Prof. Roscoe, Prof. Shelley, Dr. Burdon Sanderson, Dr. Schuster, Dr. Voit, and Mr. R. Wylde

Their Lordships, we should say, are particular in calling attention to the fact that this is not an International *Exhibition*; the purpose and arrangement of this collection are entirely different from those of such an exhibition, which is always arranged according to countries and into which the commercial element largely enters. The arrangement here, on the contrary, is according to subjects, and the object is solely to illustrate the history and present condition of scientific apparatus. The transport of all objects has been undertaken by the English Government, and they have been handed over absolutely to the custody of the Science and Art Department.

Prefixed both to the Catalogue and the Guide is a clear and useful plan of the buildings at Kensington, showing the arrangement of the apparatus in the various galleries. Fourteen galleries in all are occupied with the collection, embracing the ground floors of the entire south and west sides, and the upper floor of the latter. Entering, as the Queen will do on Saturday, by the entrance in Exhibition Road, we come first upon A, the Educational Collections; following which are B, C, Applied Mechanics; D, Naval Architecture and Marine Engineering; E, Lighthouse Apparatus; F, Magnetism and Electricity; G, Arithmetic and Geometry; H, K, Measurement; L, Astronomy and Meteorology; these are all on the ground floor. Ascending to the upper floor, we pass through M, Geography, Geology, and Mining; N, Biology; O,

[1] "Catalogue of the Special Loan Collection of Scientific Apparatus at the South Kensington Museum." First Edition.—"Handbook to the Special Loan Collection of Scientific Apparatus." 1876.

Conference Room; P, Chemistry; Q, Light, Heat, Sound, and Molecular Physics.

The number of exhibitors—governments, societies, departments, and individuals—amounts to about 1,000, and the collection contains altogether somewhere about 15,000 objects, arranged in this first edition of the catalogue, under 4,576 heads. The countries represented are the United Kingdom, Austro-Hungarian Empire, Belgium, France, Germany, Holland, Italy, Norway, Russia, and Switzerland. The list from Spain is not yet received, and the fact that America is occupied with her own Centennial Exhibition sufficiently accounts for her absence, though the American Government heartily sympathises with the object of the collection. In the catalogue the objects are arranged under twenty-one sections; the numbers enable the visitor at once to identify each object or group of objects, and in most cases the appended descriptions are sufficiently detailed to enable anyone to understand the purpose and construction of the apparatus. In many cases the descriptions are as minute as in a special text-book.

Under Section 1, Arithmetic, are described various Slide-rules, 19 in all, 26 Calculating Machines, including Babbage's famous "Difference Engine," which is described in considerable detail, besides some interesting and ingenious miscellaneous apparatus. Under Section 2 are classed instruments used in Geometrical Drawing, Instruments for tracing Special Curves, Models of Figures in Space, and a collection of Plücker's models of certain quartic surfaces, contributed by the Mathematical Society.

As might be expected in a collection of scientific apparatus, those connected with Measurement, Section 3, occupy a large space: there are upwards of 350 entries under this head, comprising, besides a variety of extremely interesting and curious special collections, apparatus for Measurement of Length (nearly 100 entries) of Area, of Volume, of Mass, of Velocity, of Momentum, of Force, of Work, of Angles, and of Time (80 entries); many of the objects in this section are of a remote antiquity, and not a few are connected with scientific discoveries of the highest importance.

Section 4, Kinematics, Statics, and Dynamics, is a very full and instructive one; it is impossible to give here anything like an idea of the nature and variety of the apparatus exhibited under this head. It contains 22 sub-sections and sub-sub-sections, including several of 'sGravesande's apparatus, apparatus illustrating the Mechanical Powers, Pendulums and Gyroscopes, Vibrations and Waves, Falling Bodies and Projectiles, and other departments of the very comprehensive section, including 54 Crank Trains, 50 Toothed-wheel Trains, and 67 Ratchet Trains.

To many, Section 5, Molecular Physics, will be intensely interesting; its six sections contain 110 entries; the Air-pumps and Pneumatic Apparatus alone numbering 44. Osmose Dialysis and Diffusion, Condensation of Liquids and Solids, and Hydrometers, are some of the other subjects illustrated here.

Sections 6, 7, and 8, Sound, Light, and Heat, are of course among the most important, the catalogue containing 410 entries under these heads. There are apparatus illustrating the Sources, Measurement, and Interference of Sound, and a variety of other phenomena, including Musical Sounds; in Section Light, under the head Selectors, there are 36 groups of apparatus connected with the Spectroscope, and 30 to illustrate Polarisers, besides Photometers, Radiometers, apparatus bearing on Reflection, Refraction, and Diffraction. Photography is a varied and interesting sub-section. The multitude of apparatus connected with Heat is classified under Sources of Heat, Thermometry (56 entries), Calorimeters, Pyrometers, Freezing Machines, Conductors, &c.

Sections 9 and 10, Magnetism and Electricity, are likely to prove two of the most attractive, as they are certainly among the most important. All departments of these subjects—and how varied they are even scientific men may be astonished to learn—are illustrated with great fulness; the number of entries in the Catalogue is 650, commencing with the greatest natural magnet yet known, weighing, with armature, 152 kilograms, sent by the Teyler Foundation, Haarlem, and concluding with a minute description of the Polar Light Apparatus, by Prof. Lemström. Of apparatus connected with Electricity the variety is astounding. Friction and Induction Machines, Galvanic Batteries (there are 32), Thermo-Electric Batteries, Induction Coils, Magnetic-Electric Machines, and other modes of producing Electricity or Electric Currents, are abundantly represented. So, also, apparatus for producing, collecting, observing, regulating, and measuring electricity; of Galvanometers alone there are 43. In the Electrical Section, no doubt the most attractive department to the general public will be that devoted to apparatus for the application of Electrical principles to practical purposes, illustrating, as it does, every stage in the progress of the Electric Telegraph. The Catalogue in this department contains 204 entries of Telegraphic apparatus alone, not to mention the various other applications of electricity to military and other purposes.

Astronomy, Section 11, is at the same time one of the oldest and one of the most popular of the sciences, and therefore the apparatus in the section will probably have more than an average number of visitors. The historical interest of this section is probably greater than that of any other, and it is significant of the importance attached by Italy to this Collection that she has parted with, even for a short time, those precious relics of Galileo that cannot fail to excite the veneration of all beholders. But besides these there are many other instruments of great historical interest, from the Suspension Astrolabrum, made in 1525, sent by Prof. Buys Ballot of Utrecht, down to the latest form of spectroscope, and a relief landscape of the moon. Celestial photography is largely represented, both by its instruments and results, and teachers will be much interested in the varied and ingenious apparatus that have been devised for the practical teaching of astronomy.

Of the multitude of objects in Section 12, Applied Mechanics, it would be impossible with our space to give any satisfactory idea. The catalogue contains under this head 470 entries in all, many of which, as indeed is the case in all the other sections, include a considerable number of separate pieces of apparatus. Of Prime Movers alone there are 66 groups, ranging through many forms from a collection of the Original Models of Steam Engines and other machines of James Watt, downwards.

Under the comprehensive head of Application of the Principles of Mechanics to Machinery, as employed in the Arts, the catalogue gives a description of 136 varieties of apparatus, from the first type-composing machine invented by Alex. Mackie, which comes from Dundee, down to the latest forms of link-work.

Chemistry, Section 13, is of course one of the most prominent and important sections in the whole collection. When we say that the catalogue contains 360 entries under this head, we give very little idea of the multitude and variety of objects which have been brought together to illustrate the methods and results of the all-pervading science. The first entry is the apparatus employed by John Dalton in his researches, and is accompanied by a long descriptive and historical notice by Prof. Roscoe. Cavendish, Davy, Faraday ("Original tubes containing gases liquefied by Faraday," must be an exciting entry to many chemists), Wollaston, are names attached to some of the apparatus of historical interest, of Models, Diagrams, Apparatus, &c., employed in teaching Chemistry there is no end, and all the infinite variety of special chemical apparatus is amply illustrated, there being upwards of 200 entries under this head, representing probably more than ten times that number of separate objects.

The rapid advances and present complexity and comprehensiveness of Meteorological science are shown by the catalogue to be illustrated with wonderful fulness in the collection. The endless variety of Barometers, Thermometers, Anemometers, Rain-gauges, Hygrometers, Self-recording Instruments, Ozonometers, and other apparatus used in meteorology, will excite the astonishment of all but specialists. The Scottish Meteorological Society is a large contributor in this section, and some of their intensely practical graphic results must appeal to the blindest utilitarian.

Geography is sure to be a popular section, and we can only say that in its various sub-divisions are objects calculated to rouse the interest of the most incurious. The methods, apparatus, and results of the various surveys of this country and of India are illustrated in the greatest detail, and now that the *Challenger* is nearing our shores, many will be curious to see some of the apparatus with which her important ocean-researches have been conducted. There is a vast variety of surveying apparatus with which Geography obtains her apparently simple results, and of Maps, Charts, and Plans of all kinds the list is endless. Everyone must inspect with very curious feelings the original Journals, Log-books, &c., kept by celebrated English navigators from Dampier downwards, not to mention the valuable MS. Maps of Livingstone and other celebrated explorers.

Geology, Mining, and Mineralogy, Sections 16 and 17, are well represented. They include Geological Instruments and Apparatus; Maps, Sections, Diagrams, &c., lent by the Geological Survey; illustrations of the Sub-Wealden boring; various Relief-maps and Models illustrating Geological Phenomena all over the world; Fossils and Specimens of all kinds, natural and artificial; Mining Instruments and accessories, including a case of 46 varieties of Safety-lamp; Blowpipe Apparatus; Minerals, Diagrams, Models of Crystals, &c.

The Section of Biology has 500 entries, embracing probably eight times that number of separate objects. Of microscopes and accessory apparatus, there are upwards of 150 from the Compound Microscope of Zacharias Janssen, spectacle-maker, at Middleburg, Netherlands, constructed about 1590, down to the latest and most complicated form of this now indispensable and powerful instrument. Then there are many specimens of the curious and ingenious apparatus employed in Physiological Optics, Weighing and Measuring Apparatus, Apparatus for investigating the functions of Circulation and Respiration, of Muscles and Nerves, and an endless variety of Diagrams, Models, Preparations, and other appliances for instruction in Biology. Wolf's Collection of 106 Original Water-Colour Drawings illustrating the new and rare animals in the Zoological Gardens will prove nearly as attractive as the originals themselves.

Under Educational Appliances, Section 19, there are apparatus for practical instruction in Science in every department, including a very fine and large collection of apparatus for instruction in Physical Science, contributed by the Committee of the Pedagogical Museum, Russia. This section contains upwards of 550 entries.

Last of all comes the Collection of Apparatus and Photographs illustrating Italian Science, more especially in the departments of Physics, Mechanics, and Astronomy. There are many objects here deserving special mention, but our space forbids further detail. We have already referred to Galileo's instruments, and besides these there are many others of great antiquity and of much interest in connection with the progress of scientific apparatus.

This rapid glance at the contents of the Catalogue will give but a faint idea of the rich feast in store for those who during the next few months will be attracted to the South Kensington galleries. To give anything like an adequate idea of the contents of the collection would take a long series of articles.

We have said that the Catalogue, even in its present incomplete and rough form, is something more than a mere list of titles; it is very largely descriptive. But something more was required to show the purpose and import and historical place of the multitude of separate instruments in the various sections. This want is supplied in the admirable Handbook, of 340 pages, consisting of a series of descriptive and historical articles on the various sections by some of the most eminent living British men of science. It will be enough if we give here the names of the authors and the subjects of which they treat. In value the Handbook should be put alongside the Admiralty Manual issued to the Arctic Expedition; though probably no such unique collection of scientific memoirs was ever before put within reach of the public. The first paper is by Prof. Clerk-Maxwell, being "General Considerations respecting Scientific Apparatus;" Prof. Maxwell has also a paper in his own special domain, Molecular Physics. Prof. H. J. S. Smith writes on "Arithmetical Instruments" and "Geometrical Instruments and Models." Prof. W. K. Clifford also contributes two papers, on "Instruments used in Measurements" and on "Instruments illustrating Kinematics, Statics, and Dynamics." Then there are papers by Dr. W. H. Stone, on "Acoustical Instruments," by Mr. W. Spottiswoode on "Optical Instruments," by Capt. Abney on "Photographic Printing Processes," by Prof. Tait on "Instruments employed in Heat Investigations;" two

papers by Prof. Carey Foster on "Magnetic Apparatus" and "Electrical Instruments;" a paper by Mr. J. Norman Lockyer on "Astronomical Instruments;" by Prof. Goodeve on "Applied Mechanics," by Prof. McLeod on "Chemical Apparatus and Products," by Mr. R. H. Scott on "Meteorological Instruments." "Geographical Instruments and Maps" are illustrated historically and descriptively in four papers by Mr. C. R. Markham, and one by Capt. J. E. Davis. Prof. Geikie treats of "Geology," Mr. Warington Smyth of "Apparatus used in Mining," Prof. Story Maskelyne of "Crystallography and Mineralogy," Prof. Huxley of "Instruments employed in Biological Research," and Mr. H. C. Sorby of "Microscopes." Is not this strong enough evidence of the genuine interest which British men of science take in this Loan Collection of Scientific Apparatus?

There is only one drawback to our joy in seeing this collection at last completed and ready to be thrown open to the public: it is after all only a "loan" collection, and in a few months must be disorganised, and the apparatus returned to their owners. We have some reason to hope, however, that this will not be the end of all the labours of the eminent men who have exerted themselves to make the collection a success; we are persuaded that in time it will be succeeded by a permanent collection, which will form a Science Museum on an equal footing with the other Museums supported by Government. The Introduction to the Handbook says:—

"The Lord-President of the Council, the Duke of Richmond, and the Vice-President, Viscount Sandon, in explaining the objects of the collection, took occasion to refer to the recommendations of the Royal Commission on Scientific Instruction, with regard to the creation of a Science Museum. Their Lordships stated their conviction that the development of the Educational and certain other Departments of the South Kensington Museum, and their enlargement into a Museum somewhat of the nature of the Conservatoire des Arts et Métiers in Paris, and other similar institutions on the Continent, would tend to the advancement of science, and be of great service to the industrial progress of this country."

We cannot doubt that neither Government nor the public, after having substantial evidence of the value and important results of a Science Museum in this Loan Collection, will rest satisfied until this country is at least on an equal footing in this respect with our neighbour France. It seems to us that a permanent Science Museum will be the natural outcome of the unexpectedly magnificent collection which the Queen will open on Saturday; it cannot fail to make the public at large conscious of a serious want which for long has been painfully felt by men engaged in scientific research, both pure and applied.

DIFFUSION OF GASES THROUGH ABSORBING SUBSTANCES

Ueber die Diffusion der Gase durch absorbirende Substanzen. Habilitationsschrift der Mathematischen und Naturwissenschaftlichen Facultat der Universität Strassburg, vorgelegt von Dr. Sigmund v. Wroblewski, erstem Assistanten am physikalischen Institute. (Strassburg: G. Fischbach, 1876.)

THE importance of the exact study of the motions of gases, not only as a method of distinguishing one gas from another, but as likely to increase our knowledge of the dynamical theory of gases, was pointed out by Thomas Graham. Graham himself studied the most important phenomena, and distinguished from each other those in which the principal effect is due to different properties of gases.

The motion of large masses of the gas approximates to that of a perfect fluid having the same density and pressure as the gas. This is the case with the motion of a single gas when it flows through a large hole in a thin plate from one vessel into another in which the pressure is less. The result in this case is found to be in accordance with the principles of the dynamics of fluids. This was approximately established by Graham, and the more accurate formula, in which the thermodynamic properties of the gas are taken into account, has been verified by the experiments of Joule and Thomson. (Proc. R. S., May, 1856.)

When the orifice is exceedingly small, it appears from the molecular theory of gases that the total discharge may be calculated by supposing that there are two currents in opposite directions, the quantity flowing in each current being the same as if it had been discharged into a vacuum.

For different gases the volume discharged in a given time, reduced to standard pressure and temperature, is proportional to—

$$\frac{p}{\sqrt{s\theta}}$$

where p is the actual pressure, s is the specific gravity, and θ the temperature reckoned from -274° C.

When the gases in the two vessels are different, each gas is discharged according to this law independently of the other.

These phenomena, however, can be observed only when the thickness of the plate and the diameter of the aperture are very small.

When this is the case, the distance is very small between a point in the first vessel where the mixed gas has a certain composition, and a point in the second vessel where the mixed gas has a quite different composition, so that the velocity of diffusion through the hole between these two points is large compared with the velocity of flow of the mixed gas arising from the difference of the total pressures in the two vessels.

When the hole is of sensible magnitude this distance is larger, because the region of mixed gases extends further from the hole, and the effects of diffusion become completely masked by the effect of the current of the gas in mass, arising from the difference of the total pressures in the two vessels. In this latter case the discharge depends only on the nature of the gas in the vessel of greater pressure, and on the resultant pressures in the two vessels. It consists entirely of the gas of the first vessel, and there is no appreciable counter current of the gas of the other vessel.

Hence the experiments on the double current must be made either through a single very small aperture, as in Graham's first experiment with a glass vessel accidentally cracked, or through a great number of apertures, as in Graham's later experiments with porous septa of plaster of Paris or of plumbago.

With such septa the following phenomena are observed:—

When the gases on the two sides of the septum are

different, but have the same pressure, the reduced volumes of the gases diffused in opposite directions through the septum are inversely as the square roots of their specific gravities.

If one or both of the vessels is of invariable volume, the interchange of gas will cause an inequality of pressure, the pressure becoming greater in the vessel which contains the heavier gas.

If a vessel contains a mixture of gases, the gas diffused from the vessel through a porous septum will contain a larger proportion of the lighter gas, and the proportion of the heavier gas remaining in the vessel will increase during the process.

The rate of flow of a gas through a long capillary tube depends upon the viscosity or internal friction of the gas, a property quite independent of its specific gravity.

The phenomena of diffusion studied by Dr. v. Wroblewski are quite distinct from any of these. The septum through which the gas is observed to pass is apparently quite free from pores, and is indeed quite impervious to certain gases, while it allows others to pass.

It was the opinion of Graham that the substance of the septum is capable of entering into a more or less intimate combination with the substance of the gas; that on the side where the gas has greatest pressure the process of combination is always going on; that at the other side, where the pressure of the gas is smaller, the substance of the gas is always becoming dissociated from that of the septum; while in the interior of the septum those parts which are richer in the substance of the gas are communicating it to those which are poorer.

The rate at which this diffusion takes place depends therefore on the power of the gas to combine with the substance of the septum. Thus if the septum be a film of water or a soap bubble, those gases will pass through it most rapidly, which are most readily absorbed by water, but if the septum be of caoutchouc the order of the gases will be different. The fact discovered by St. Claire-Deville and Troost that certain gases can pass through plates of red hot metals, was explained by Graham in the same manner.

Franz Exner [1] has studied the diffusion of gases through soap bubbles, and finds the rate of diffusion is directly as the absorption-coefficient of the gas, and inversely as the square root of the specific gravity.

Stefan [2] in his first paper on the diffusion of gases has shown that a law of this form is to be expected, but he says that he will not go further into the problem of the motion of gases in absorbing medium, as it ought to form the subject of a separate investigation.

Dr. v. Wroblewski has confined himself to the investigation of the relation between the rate of diffusion and the pressure of the diffusing gas on the two sides of the membrane. The membrane was of caoutchouc, 0·0034 cm. thick. It was almost completely impervious to air. The rate at which carbonic acid diffused through the membrane was proportional to the pressure of that gas, and was independent of the pressure of the air on the other side of the membrane, provided this air was free from carbonic acid. The connection between this result and Henry's law of absorption is pointed out.

[1] "Pogg. Ann," Bd. 155.
[2] "Ueber das Gleichgewicht u. d. Diffusion von Gasgemengen." Sitzb. der k. Akad. (Wien), Jan. 5, 1871.

The time of diffusion of hydrogen through caoutchouc is 3·6 times that of an equal volume of carbonic acid. The diffusion of a mixture of hydrogen and carbonic acid takes place as if each gas diffused independently of the other at a rate proportional to the part of the pressure which is due to that gas.

We hope that Dr. v. Wroblewski will continue his researches, and make a complete investigation of the phenomena of diffusion through absorbing substances.

J. CLERK MAXWELL

MACALISTER'S "ANIMAL MORPHOLOGY"

An Introduction to Animal Morphology and Systematic Zoology. Part I.—Invertebrata. By Prof. Alexander Macalister, M.B. (Longmans, Green, and Co., 1876.)

HOW many of those who are not of an extra systematic turn of mind, when they review their reading in any special line of research, have continually to regret that they have not had the industry to abstract as well as to classify the various monographs and papers they have perused, and to preserve them in a united form for future reference. Those of us who are zoologists may lay aside some of our misgivings on this score; for one among us, an exhaustive reader and an acute appreciator of the relative importance of facts, has so widely distributed his literary investigations, at the same time that he has made it a principle to keep a memorandum of those points which have most impressed him, that he has felt justified —quite correctly, as all his readers we are convinced will agree—in placing his compilation at the disposal of the scientific public. The volume on the Invertebrata, now before us, fills between four and five hundred closely printed octavo pages.

It is evident that a work constructed on the principles above indicated must be of too exhaustive and too abstruse a nature for the commencing student. It would be impossible for any author so to combine primary definitions and first principles with elaborate detail as to produce a book which would appeal to the tyro as well as the advanced zoologist. Prof. Macalister's "Introduction to Animal Morphology" must be therefore looked upon as an introduction to the science proper, to be read by the second-year student, or to be interleaved for further annotation by the specialist. To teachers of Zoology it will be found invaluable on account of the great fund of information it contains in a highly condensed form, also because in nearly all cases the *name* of the authority for each important fact is associated (in brackets) with his observation. In such a work we think that no better method could have been employed. It would have greatly overloaded the pages if full references had been given; and now that the invaluable Catalogue of Scientific Papers, published by the Royal Society—in which the publications are arranged under the *names* of authors—is within reach of all, in the libraries of the learned societies, if not elsewhere, it is a matter of no great difficulty for anyone who is particularly interested in any special detail, to find which is, and refer to, the monograph or shorter communication in which the point in question is embodied.

There is a small detail in association with the printing of the work, a modification of which in the second volume

would be an immense advantage. Prof. Macalister heads each page with the words, "Introduction to Animal Morphology." In so doing he seems to have entirely overlooked the fact that the object of the heading is to give some notion as to what is to be found below it, and not the title of the work itself. Why he has not followed the ordinary method of placing on the top of one of each two pages the subject of the chapter, and on the other further detail, we are at a loss to understand, and suffer accordingly in attempting to make any particular reference.

The first seven chapters of Prof. Macalister's work are on general subjects: protoplasm, general morphology, histology, tectology (individuality and the formation of organs), reproduction, and the distribution of animals. There are certain statements in the last of these with which we cannot quite agree. That Patagonia should be entirely removed from the Neotropical Region and placed together with the Southern Circumpolar Land in a special Antarctic, seems very much at variance with known facts. Why the Polar Bear should be only mentioned in association with the Nearctic Circumpolar Region; the Aard-vark, Manis, and Manatee with the Guinean; the Catarrhine Monkeys with the Indian; Bennett's Cassowary with the Australian; the Birds of Paradise with the Indo-Malay, we are at a loss to comprehend.

In association with the doctrine of the origin of species we are told that, "as a natural deduction from evolution, we have *Dr. Haughton's* law, that all structures are arranged so as to give the maximum of work possible under the given external conditions." This law is, however, a natural deduction from the theory of natural selection, not from evolution; it not being evolution, *per se*, but the struggle for existence which brings to the foreground the most economical animal machinery. It may also be mentioned that there are still wanting some important links in the chain of reasoning which explains the diminution of organs, like the wings of birds, in small islands. These seem to be lost on account of the reduction of the struggle for existence, mammals not being on the ground to contest the field. Dr. Haughton's law, therefore, no longer applies apparently. Why then are the wings lost?

The classification adopted is that of Haeckel modified, the Metazoa being primarily divided into the two subseries, Polystomata (Sponges) and Monostomata; the Cœlenterata being removed from the Porifera, and included with the other forms in which there is but one aperture of ingress into the body-cavity. No very special stress is laid on the vertebrate affinities of the Tunicata, which are included in the sub-kingdom Vermes. Of their development we read that "in Ascidia and Phallusia the segmented yelk assumes its mulberry form, hollows within, and appears as a spherical, cellular body (blastula); a groove indents one side of this; the lips of the groove rise and close it in, except in one spot, and thus the body becomes bicavitary, the dorsal groove contracts, and the nerve ganglion develops either within it or in its close vicinity. On a plane between the dorsal neural cavity thus formed and the ventral space, a double row of large cells appears, which extends into the tail, and forms an axis for that organ. These cells resemble those of the chorda dorsalis of Vertebrates, and have a similar relation to the neural and visceral cavities of the primarily bicavitary body to that possessed by the dorsal chord. Upon these phenomena, observed by Kowalewsky, Kupffer, and others, is rested the theory of relationship of Tunicates and Vertebrates, which is strengthened by the setting apart here of a portion of the digestive canal for respiratory purposes." This quotation illustrates the condensed manner in which the whole work is written and the way in which single words are frequently modified to do the duty of whole sentences. As a second illustration of the same method when employed with reference to the sub-kingdom Cœlenterata, one in which name-coining has arrived at a worse pitch even than in systematic botany—the following sentence will suffice:—"The alternation of generations may be binary (hydranth, gonophore, + hydranth, gonophore, &c.), or ternary (hydranth, blastostyle, gonophore, + *h*, *b*, *g*, &c.), or quaternary (hydranth, blastostyle, blastocheme, gonocheme, + *h*, *b*, *b*, *g*, &c.); or even more complex if the hydranths be heteromorphic." The Mollusca are treated of between the Vermes and Arthropoda, it being remarked of them that "their structure can be easily understood by regarding them as Vermes with no articulated appendages, modified by unequal lateral development, and by a fusion of the metameres," although "we know as yet of no absolute passage forms or direct synthetic types." This being the case, we cannot understand how each of these major groups can be regarded as a sub-kingdom.

The author, in his preface, regrets that, owing to the long time that the work (written in 1873) has been going through the press, he has not been able to introduce into it references to recent discoveries, which explains several important omissions. Notwithstanding this, we are convinced that all zoologists will agree that the work is a most valuable addition to the literature of general animal morphology.

OUR BOOK SHELF

Introductory Text-book of Physical Geography. By David Page. Eighth Edition. (Blackwood and Sons, 1876.)

INTRODUCTORY text-books on Physical Geography are not numerous, and if we may judge by the calls for new editions, this one is growing in favour. It certainly gives in a short and handy form the most important facts of the subject—and in the descriptive part it is merely a question of the selection of the most important, and in this respect we think the selection judicious, as indeed it would appear to have been found. Dr. Page comes to Physical Geography from the side of Geology, and his readers reap the benefit of it, in the chapters relating to the structure of the earth, and to the work of rivers, and to the positions of mountain ranges, which are very good. In many other respects too, the book is worthy of the support it receives, the facts being told clearly, concisely, and for the most part truly.

We cannot help, however, drawing attention to one or two points which we think would at least have been differently worded if the author had approached his subject from a physical side in his explanation of phenomena. Thus we are told with reference to water, that "when converted into steam it occupies 1,696 times more space with a specific gravity of only ·622." The only standard of specific gravity mentioned is water at 62° F., and a physicist might ask at what *pressure* is the steam?

Again, we read, "the atmosphere being the medium

through which the sun's heat is conveyed to and from the earth, the lower and denser strata absorb the greatest amount, and are necessarily the warmer;" a sentence of which a teacher would score almost every word. Again, on the subject of dew, we read that "substances like glass, &c., which *rapidly* lose their own heat and *slowly* acquire that of others are susceptible of being copiously bedewed." The italics are ours. And once more, "when the temperature of the air is reduced below that of the invisible vapour it contains, the moisture becomes visible." These extracts could be multiplied till we might wonder if it is really a book on *Physical* Geography we are reading. But these are serious defects, and we wish they could be altered. By the side of them it is of less consequence that while we read in the Preface that "this revision embraces all that is important in recent discovery;" yet on turning to the temperature of the sea, where the most important changes have taken place in our knowledge, we are still referred to Sir James Clarke Ross, and told that the ocean has below the surface a uniform temperature of $39\frac{1}{2}°$, for which at the equator we must descend deeper than anywhere else. We can scarcely imagine that any amount of clearness will atone for these things; let us hope they will be seen to before edition the ninth is required.

The Flora of South Australia. By R. Schomburgk, Ph.D., Director of the Botanic Gardens, Adelaide. (W. C. Cox, 1875.)

WE have here a complete list of the indigenous flora of South Australia, both tropical and extra tropical, with some general remarks prefixed. The most predominant natural orders in the colony are Leguminosæ. Myrtaceæ, Compositæ, Proteaceæ, Cruciferæ, Rubiaceæ, and Gramineæ. The genera and species are remarkably circumscribed in area; many are found in one spot alone. The colony is singularly devoid of native edible fruits and roots; on the other hand it produces abundance of valuable timber-trees and of plants suitable for the manufacture of paper and other fibres, and for the production of dyes; but most of the valuable crops are naturalised plants, introduced from Europe or other parts of the world. A. W. B.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Theory of Electrical Induction

IN NATURE, vol. xiii. pp. 437, 475, Prof. Paul Volpicelli gives an exposition of the two theories of electric induction, containing copious references to the writings of electricians, and numerous experiments of his own. It is remarkable, however, that he has not only omitted all reference to the works of Poisson, Green, Thomson, Beer, Betti, &c., who have studied the mathematical theory of induction, but he has not even introduced the word potential into his exposition, unless we are to take the word tension in the sense of potential, where he says that a certain portion of electricity possesses tension while another portion does not.

The result of this mode of treating the subject without calling in the aid of those ideas and phrases which the progress of science has developed, is to convey the impression that the whole theory of induction of electrification on the surface of conductors is still in a very imperfect and vague condition, whereas there is no part of electrical science in which we can trace more distinctly the correspondence, quantitative as well as qualitative, of the phenomena with the general laws of electricity. It appears, however, from what M. Volpicelli says, that an erroneous theory is still generally adopted in treatises on physics and electricity, and that it ought to be superseded by a more correct theory first proposed by Melloni.

Both theories admit that if an insulated conductor, without charge, is acted on by a charged inductor, the surface becomes electrified, oppositely to the charge of the inductor on the parts nearest the inductor, and similarly to the charge of the inductor on the parts farthest from it. The first of the two theories, however, asserts that both these electricities are "endowed with tension," whereas the second, that of Melloni, asserts that the electricity of the same kind with that of the inductor is alone "endowed with tension," while the other kind of electricity is entirely "latent or dissimulated."

The only sense which we can attach to the word "tension" as thus used, is that which modern writers mean by "potential," or potential function, the difference being that the word tension is often used in a vague manner, whereas potential is strictly defined.

Thus a point in space is said to have a certain electric potential, and since all points of a conductor in electrical equilibrium have the same potential, we speak of the potential of the conductor. But we do not speak of the potential of a charge of electricity, or of electricity being endowed or not endowed with potential. Such language would only lead us into error.

Let us suppose the inductor to be charged positively and the induced body to be insulated and originally without charge. Then, since its insulation prevents any electric communication with other bodies, its total electrification must remain zero, or there must be as much positive electrification as there is negative.

Hence for every line of electric force which proceeds from the inductor and falls on the induced body, there is another which proceeds from the induced body and falls on the walls of the room, or on some other body whose potential is zero. The potential of the induced body must therefore be intermediate between that of the inductor and that of the walls of the room, which is generally taken as zero. The potential of the induced body is therefore positive.

There is thus on the surface of the induced body a region nearer the inductor which is negatively electrified, and a region further from the inductor which is positively electrified. These regions are divided by a neutral line on the surface, which is the section of the surface by an equipotential surface in space which has the same potential as the induced body. The total charges on these two regions are exactly equal but of opposite signs.

If a small insulated conductor is placed in contact with any part of the surface and removed, it will be found to be electrified in the same way as the part of the surface with which it was in contact. A fine short needle point, or a burning pastille, placed on any part of the surface will dissipate the kind of electricity which exists on that part of the surface. See Riess, "Reibungs Elektricität," Art. 247.

If any part of the induced body is placed in electrical connection with the earth by touching it with a fine wire, positive electricity will be discharged, and the potential of the induced body will be reduced to zero. This will be the case whether the part touched be positively or negatively electrified. The quantity of electricity discharged will be the product of the potential of the induced body into its electric capacity.

After this discharge every part of the surface of the induced body will be negatively electrified, but the parts nearer the inductor more than those which are further from it.

In the mathematical treatment of the subject Thomson has found it convenient to divide the electrification into two parts, each distributed over the induced body according to its own law.

(α) The induced electrification when the induced body is connected to earth, and the charge of the inductor is E. This electrification is negative on every part of the surface, but the density is greatest next the inductor.

(β) The electrification when the induced body has a potential P, and the inductor, still in the same place, has no charge. This electrification is positive on every part of the surface.

From a knowledge of these two distributions it is easy to determine a third, in which the total electrification is the algebraical sum of (α) and (β), and in which the value of P is such that the total electrification is zero.

We might then assert that the electrification (β) is free, because it will be discharged if the body is connected to earth, but that the electrification (α) is latent or dissimulated, because it will not be discharged to earth.

The only danger of this mode of exposition is that it may suggest to a beginner the notion that electricity, like water and other substances, may exist in different physical states, in some of which it is more mobile than in others.

This idea of variation of quality once introduced into the

mind will tend to prevent the student from forming any clear and distinct conception of the phenomena.

Let us now examine how far M. Volpicelli's experimental skill and extensive reading have enabled him to give an accurate account of the phenomena, and how far he may have fallen into error from not availing himself of the idea of electric potential, but continuing to employ that of latent electricity.

Melloni, in his exposition has represented the homonymous electrification (β) as greater on the side of the induced body further from the inductor. The fact, however, is that the electrification is distributed in the same way as it would be if the inductor were in its actual position and insulated, but without charge. It will therefore be densest on the projecting parts of the induced body; but if the two extremities of this body are geometrically similar, and if the inductor is made of a conducting substance, it will be somewhat denser on the extremity (1) next the inductor, because the surface of the inductor itself (c) will become electrified and the electricity on the side next to B will be negative.

But the inequality of the distribution of the negative electrification (α) is so much greater that it completely masks that of (β), so that from an experimental point of view we must regard this error of Melloni as a very trifling one.

The next point we must notice is the mode in which objection (3) is expressed. It is as follows:—

"(3) Because of the two kinds of electricity which coexist upon the induced insulated body, only the homonym of the inductor is dissipated *by contact with the air*." (The italics are our own.)

We have no evidence whatever that electricity is ever dissipated by contact with air, whether dry or moist, unless the electric density is so great that a disruptive discharge takes place in the forms of "glow," "brush," or "spark," from some point connected with the electrified body.

If the electrified body and the surrounding conductor have rounded surfaces, and if the potential is moderate, it appears from the experiments of *Boltzmann*[1] that no measurable quantity of electricity passes through air or other gases, even when greatly rarefied, and when the experiment is continued for fourteen hours.

I have myself been unable to detect any conduction through a stratum of still air of two millimetres thickness, even when the temperature was raised to a red heat, and when steam or the vapour of mercury or of sodium was introduced between the oppositely electrified surfaces. If, however, any dust was introduced, there was a considerable effect arising from convection by the solid particles.

The cause of the powerful electrical effect of the stream of heated matter rising from a burning flame or from a red-hot ball, as in Guthrie's experiments, requires a special investigation.

The dissipation of the charge of insulated bodies which we actually observe seems to depend principally on the insulating supports on which they are placed, and if these are of good glass the conduction is almost entirely due to moisture on the surface of the glass. If the air which is in contact with the glass insulator is perfectly dry the dissipation of electricity will be extremely small even when the air in contact with the electrified body itself is loaded with moisture.

It is not, therefore, by contact with the air that the electricity escapes, but by conduction to the earth along the so-called insulating supports, and the effect of this conduction is of course to reduce the potential to zero by discharging electricity of the same kind with that of the inductor.

We come next to the fourth of the five facts mentioned under the head of the First Experiment. It is stated as follows:—

"4. Points applied to the extremity of the cylinder nearest to the inductor allow only the homonym of the inductor to escape, and not at all the opposite electricity."

This will be the case if the point is electrically connected with the earth, and made to approach any part of the surface of the cylinder; but if, as the words seem rather to imply, the point is attached to the cylinder and projects into the air, then the statement is exactly opposite to that given by Riess in Art. 247 of his book, who correctly tells us that if the cylinder has a sharp point at one end, then if the point is turned towards the inductor, the cylinder becomes charged similarly to the inductor, whereas if the point is turned away from the inductor, the cylinder becomes charged oppositely to the inductor, the discharge from the point being always of that kind of electricity which exists on the part of the cylinder where the point is placed.

The fifth fact stated to be established by the experiment is—

"5. Induced electricity of the first kind (opposite to that of the inductor) is not transferred from the induced body to the inductor, but the electricity of the inductor may certainly be transferred to the induced body."

For the sake of distinctness, let us say that the inductor is positive, then it is here asserted that negative electricity does not pass from the cylinder to the inductor, but that positive electricity passes from the inductor to the cylinder.

If M. Volpicelli can give us an experimental method of distinguishing between the passage of negative electricity from *B* to *A*, and the passage of positive electricity from *A* to *B*, we may expect to learn more of the nature of electricity than any of our physicists have hitherto even hoped for.

Cherry Blossoms

IN the last number of NATURE (vol. xiv. p. 10), Mr. Pryor states that the flowers of the wild cherry are bitten off in large numbers in much the same manner as I formerly described in the case of the primrose. Some days ago I observed many cherry blossoms in this state, and to-day I saw some actually falling. I approached stealthily so as to discover what bird was at work, and behold it was a squirrel. There could be no doubt about it, for the squirrel was low in the tree and actually had a blossom between its teeth. It is none the less true that birds likewise bite the flowers of the cherry tree.

Down, Beckenham, May 6 CHARLES DARWIN

The Pollen of the Cherry

THE practice of the indefinite reproduction of woodcuts by means of *clichés* has frequently given rise to the repetition of erroneous drawings in one scientific text-book after another. Botanical text-books seem to have suffered especially in this way, in consequence of the great dearth of new and original illustrations by which they are characterised. Many botanical students must have been puzzled by the peculiar appearance presented by the pollen of the cherry in a very familiar drawing. It is hardly sufficiently explained that "the escape of the fovilla in an irregular jet," as there represented, has nothing to do with the process of fertilisation, but is an altogether abnormal phenomenon dependent on the bursting of the pollen-grain in [illegible] artificial moistening. The shape of the pollen-grain, as given, for example, in Balfour's "Class-book of Botany," Le Maout and Decaisne's "General System of Botany," and Dr. Hooker's Science Primer "Botany,"[1] is also incorrectly indicated. The perfectly spherical form represented in the drawing is almost, if not altogether, confined to anemophilous plants, fertilised by the wind. The cherry is, on the contrary, entomophilous, and its pollen partakes of the general character of this class of plants.

Though somewhat variable in size and form, the grains are, I believe, never spherical, but ellipsoidal, with three longitudinal furrows, as represented in the longitudinal and apical aspects, *a*, *b*, in the accompanying figure. The pollen has, however, well marked characters of its own, which distinguish it from that of allied plants, the ends often appearing truncated, as represented in *c*, and some or all of the grains more gibbous on one face than another (*d*). Most pollen grains assume a more spherical form on being moistened with water.

ALFRED W. BENNETT

[1] In Hooker's Primer there is the further complication of the accidental transposition of the figures of the cherry and evening primrose, the well-known triangular form of the latter being attributed to the former.

Spring Dynamometers

IN a former brief communication of mine on the subject of dynamometers (NATURE, vol. xiii. p. 385), suggested by an incidental remark made by Mr. Bottomley, I observed that "about three years ago Prof. Ball when introducing the C. G. S. system of units into the course of mechanics in this College had a series of dynamometers in absolute measure specially constructed for him." In reference to this statement, Dr. Ball's successor in the chair of mechanics, Prof. Hennessy, points out, in a letter to NATURE (vol. xiii., p. 466), that "the system actually employed is not that referred to by your correspondent; I generally employ the kilogram, metre, and second, and sometimes the foot, pound, and second, to measure a dynam or unit of force." It is, however, evident that the few words in my former letter did not question the merits of any particular system of units; whether the use of a mixed system of kilogram-metres and foot-pounds be an improvement upon a system now generally coming into use is a matter of opinion. And though the subject can hardly be one of much interest to your readers, I may, perhaps, remark that so far as my statement concerns Dr. Ball it is perfectly accurate; he was in the habit of using the C. G. S. system in his classes here, and I was unaware any change had been made in this respect, the following statement occurring in Prof. Hennessy's own syllabus for the present as well as last session:—"The unit of force employed is the 'dyne,' or that force which, acting uniformly upon one gramme for one second, will give it a velocity of one centimetre a second." Even if reference had been made to Prof Hennessy, one would naturally have concluded that the printed syllabus, authorised by the Department, was the one "actually employed."

Passing on to Dr. Ball's dynamometers, Prof. Hennessy remarks that "they cannot be depended upon to results within the tenth of a kilogramme"—finer readings when necessary could, no doubt, be taken by the eye, but that is really only a question for the maker, and the special purpose for which these instruments were designed: then follows the strong assertion that "spring dynamometers are totally unfit for measuring units on the C. G. S. system." As several instruments of precision depending on the tension of a spring recur to one's mind, instruments that only require proper precautions to yield extremely delicate and trustworthy results, it would be interesting to know upon what grounds Prof. Hennessy bases his emphatic and reiterated assertion. If it be merely a question of individual opinion, upon this subject hardly any authorities that could be quoted would carry such weight as Sir W. Thomson and Prof. P. G. Tait, who speak thus in their treatise on "Natural Philosophy," p. 127. "Spring balances we believe to be capable, if carefully constructed, of rivalling the ordinary balance in accuracy, while for some applications they far surpass it in sensibility and convenience."

Royal College of Science, Dublin W. F. BARRETT

The Meteors of April 20th

BETWEEN ten and twelve o'clock on the night of April 18th, Mr. W. L. Taylor, a member of the junior class in the State University, with several other gentlemen, observed an unusual number of shooting-stars. These gentlemen were returning in an open waggon from Ellettsville, eight miles north of Bloomington. No count was kept of the number of meteors observed, but the appearance was so frequent as to attract the attention of all the company. Mr. Taylor thinks the number noticed could not have been less than twelve or fifteen. From the descriptions given of the meteor tracks, I find that they were nearly conformable to the radiant of the Lyraids. The meteors were remarkably brilliant, apparently equal to stars of the first or second magnitude.

At my request Mr. Benjamin Vail, a student of the University, made observations on the nights of the 19th and 20th of April. Both nights were so cloudy, however, that a continuous watch would have been useless. About eleven o'clock on the night of the 19th, three meteors were seen in the north-west, where the sky at the time was partially clear.

Bloomington, Ind., April 26 DANIEL KIRKWOOD

American Mocking Bird

AN American mocking-bird, about a year old, which I had brought from Tennessee, has, for the past three or four weeks, been affected with an irritation round the eyes, causing the feathers to fall off and the flesh to swell; the bird is otherwise in a healthy condition, but has not sung since it has been affected with the soreness; it has the proper food supplied, and its cage is kept in a clean state; could any correspondent kindly inform me the cause and cure of the disease? M. C.

An Unusual Optical Phenomenon

THIS morning, a little after nine o'clock, the ordinary solar halo, radius about 22°, was seen. It was bright, and the red very distinct.

On turning to the north to find the direction of the cloud drift, a white band was seen extending to the north-east in one direction, and on to the west and south in the other. Its width was about that of the halo near the sun. A pair of compasses and a protractor gave the altitude of this circle about 45°. This being about the sun's altitude, the plane of the circle was no doubt parallel to the horizon and passed through the sun. I believe the circle above described to be but rarely seen.

JOSEPH GLEDHILL

Mr. Crossley's Observatory, Halifax, May 3

OUR ASTRONOMICAL COLUMN

THE BINARY λ OPHIUCHI.—An examination of the recent measures of this star, shows that neither of the orbits computed some 25 or more years since by Madler and Hind at all represents the later course of the companion, a circumstance mainly attributable, as it appears, to error in one, if not in both, of Sir W. Herschel's measures. Struve at first considered that the angle of 1783 required a correction of 180°, but at a later period he was inclined to apply a similar correction to the angle of 1802, and Dawes also believed it was the latter measure which required alteration, in order to render any orbit possible. It is upon this supposition that the orbits of Madler and Hind have been calculated: the two sets of elements are subjoined:—

	Madler	Hind.
Peri-astron passage	1790·31	1791·21
Period of revolution in years	89·01	95·88
Node	32° 42′	30° 23′
Angle between the lines of nodes and apsides on orbit	120° 4′	135° 24′
Inclination	49° 25′	49° 40′
Excentricity	0·4530	0·4772
Semi-axis major	0″·842	0″·847

Madler's orbit was published in "Untersuchungen uber die Fixsterne-Systeme, Erster Theil." The second orbit was founded upon observations to about the same year, 1849. The projection of the measures since this epoch, however, makes it apparent that the real orbit must be materially different from the above, and the star may be recommended to the attention of those who are interested in the determination of elements of the revolving double-stars.

Sir W. Herschel's papers containing his measures of double stars communicated to the Royal Society, not being always of easy access, the following extracts from his notes on λ Ophiuchi may perhaps prove useful:—

From the *Phil. Trans.*, vol. lxxv., p. 62:—

"I. 83; 1783, March 9. A very beautiful and close double-star, L. w.; S. blue; both fine colours. Considerably or almost very unequal. With 460, $\frac{1}{4}$ or $\frac{1}{3}$ diameter of S.; with 932 full $\frac{1}{3}$ diameter of S. Position 14° 30′ n. following."

From the memoir of 1804:—

"May 20, 1802, position was 20° 41′. The position March 9, 1783, was 14° 30′, north following. The difference in nineteen years and seventy-two days is 6° 11′. May 1 and 2, 1802, I could not perceive the small star, though the last of the two evenings was very fine. May 20, 1802, with 527, I saw it very well, but with great difficulty. The object is uncommonly beautiful, but it requires a most excellent telescope to see it well and the focus ought to

be adjusted upon ϵ of the same constellation, so as to make that perfectly round."

These remarks have an essential bearing upon the investigation of elements. The components must have been very close at both Herschel's epochs—if there be no mistake in the register—and this is not at first sight readily explained by the curve exhibiting the motion of the smaller star from Struve's earliest micrometrical measures in 1825 to the present date.

Herschel further remarked in 1802 that the appearance of the components was much like that of "a planet with a large satellite, or small companion," and strongly suggestive of "the idea of a connection between the two bodies, especially as they are much insulated."

THE ROTATION OF VENUS.—In a note upon the time of rotation and position of the axis of Venus, which recently appeared in this column, reference was inadvertently omitted to Flaugergues' observations at Viviers in July, 1796, which, according to a communication from Valz to the *Astronomische Nachrichten* (No. 278, vol. xi), seemed to favour Bianchini's period, and placed the north pole of Venus in longitude 321° 20′, with an elevation of 16° 28′. Details of the observations are wanting, but Valz states that Flaugergues observed with "une ancienne lunette à deux verres de 18 pieds de long, amplifiant 105 fois qu'il dit fort bonne." He also employed one of 14 feet, and a telescope said to be good, which Legentil brought from India. Valz adds: "J'ai vu le dessein original de la tache, elle était grande et de forme trapezoide arrondie, &c."

Hussey's vigorous but prejudiced defence of the extraordinary period of rotation assigned by Bianchini will be found in *Astronomische Nachrichten*, No 248.

Fritsch, of Quedlinburg, thought some observations of his in April 1801 indicated a period of 23h. 22m. (*Berliner Astronomisches Jahrbuch*, 1804, p. 213).

SONG OF THE SCREW

A MOVING form or rigid mass,
  Under whate'er conditions,
Along successive screws must pass
  Between each two positions.
It *turns around* and *slides along*—
This is the burden of my song.

The *pitch of screw*, if multiplied
  By angle of rotation,
Will give the distance it must glide
  In motion of translation.
Infinite pitch means pure translation,
And zero pitch means pure rotation.

Two motions on two given screws,
  With amplitudes at pleasure,
Into a third screw-motion fuse;
  Whose amplitude we measure
By parallelogram construction
(A very obvious deduction).

Its axis cuts the nodal line
  Which to both screws is normal,
And generates a form divine,
  Whose name, in language formal,
Is "surface-ruled of third degree."
Cylindroid is the name for me.

Rotation round a given line
  Is like a *force* along.
If to say *couple* you incline,
  You're clearly in the wrong;—
'Tis obvious, upon reflection,
A line is not a mere direction.

So *couples* with *translations* too
  In all respects agree;
And thus there centres in the screw
  A wondrous harmony
Of Kinematics and of Statics,—
The sweetest thing in mathematics.

The forces on one given screw,
  With motion on a second,
In general some work will do,
  Whose magnitude is reckoned
By angle, force, and what we call
The *coefficient virtual*.

Rotation now to force convert,
  And force into rotation;
Unchanged the work, we can assert,
  In spite of transformation.
And if two screws no work can claim,
Reciprocal will be their name.

Five numbers will a screw define,
  A screwing motion, six;
For four will give the axial line,
  One more the pitch will fix;
And hence we always can contrive
One screw reciprocal to five.

Screws—two, three, four, or five, combined
  (No question here of sex),
Yield other screws which are confined
  Within one *screw complex*.
Thus we obtain the clearest notion
Of *freedom* and *constraint* of motion.

In complex III. three several screws
  At every point you find,
Or if you one direction choose,
  One screw is to your mind;
And complexes of order III.
Their own reciprocals may be.

In IV., wherever you arrive,
  You find of screws a cone.
On every line in complex V.
  There is precisely one;
At each point of this complex rich,
A plane of screws have given pitch.

But time would fail me to discourse
  Of Order and Degree,
Of Impulse, Energy, and Force,
  And Reciprocity.
All these and more, for motions small,
Have been discussed by Dr. Ball.

ON THE TELEPHONE, AN INSTRUMENT FOR TRANSMITTING MUSICAL NOTES BY MEANS OF ELECTRICITY

MR. ELISHA GRAY recently read a paper before an American Society explaining his apparatus for experimentally how, by means of a current of electricity in a single wire, a number of notes could be reproduced simultaneously at a great distance, and how by this means also a number of telegraphic messages could be transmitted at once along a wire and separately received at the other end. One of Mr. Gray's apparatuses was exhibited in London at the last *soirée* of the Society of Telegraph Engineers by the president, Mr. Latimer Clark. The principle of the apparatus is as follows:—

A vibrating reed is caused to interrupt the electric current entering the wire a certain number of times per second and the current so interrupted at the sending end sets a similar reed vibrating at the distant end.

The sending reed is ingeniously maintained in constant vibration by a pair of intermittent electro-magnets which are magnetised and demagnetised by the vibrating reed itself.

Thus in Fig. 1 (which represents the transmitting part of the telephone and its connections for a single note), the current from the magnet battery flowing in the direction of the small arrow passes through the pair of electro-magnets A to the terminal r of the reed R, and thence by the spring contact b and the wire bZ to the battery again, completing its circuit without passing through the other pair of electro-magnets B, which are not therefore magnetised. The reed R is consequently pulled over by the electro-magnets A. But on this taking place the spring contact b is broken and the circuit is no longer completed through bZ but through the electro-magnets B, which are consequently magnetised, and tend by their induction on the reed to neutralise that of B. The reed

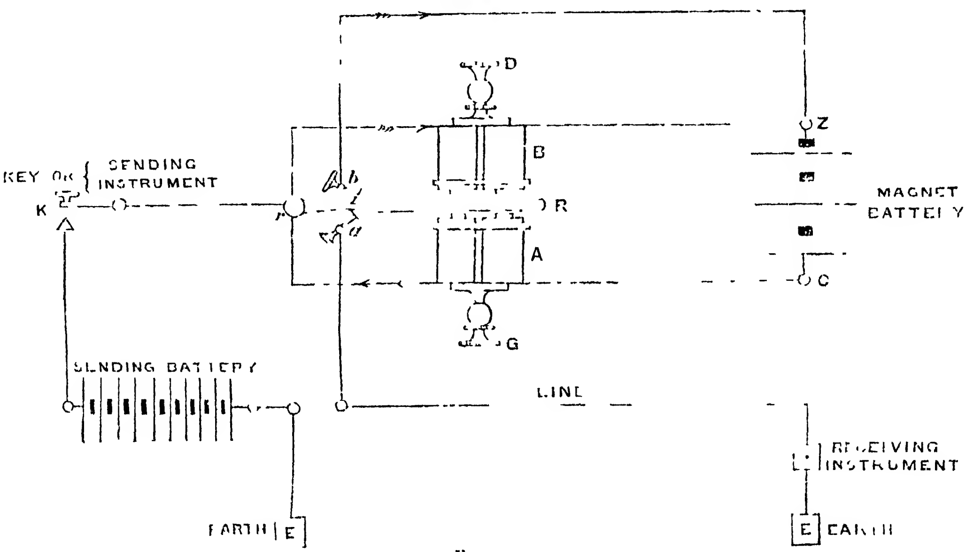

Fig. 1.

therefore springs back to its intermediary position, but in doing the contact at b is again made and the electro-magnets B again short-circuited and the reed pulled over (or rather *assisted* over, for it has its own resilience or spring) towards A; so this goes on keeping the reed in vibration between the electro-magnets and alternately making and breaking the spring contact b and also that of a, the number of contacts per second being dependant on the vibrating period of the reed.

While this is going on the reed of course emits its musical note. Two Leclanché or bichromate cells are sufficient to work the transmitter and give a good note.

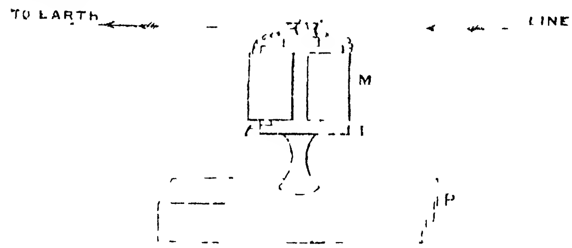

Fig. 2.

The spring contact b is to be adjusted by the screw there seen until the note emitted by the reed is both loud and pure. The magnets A and B are adjustable to or from the reed by the milled heads C and D.

The spring contact a just mentioned belongs properly to the line circuit. It is the intermittent contact which interrupts the current sent into the line. As will be seen from the diagram the circuit of the sending battery is made through the key K, the reed, and the spring contact a. On holding down the key K the current flows into the line, being interrupted, however, by the contact a as many times per second as the reed vibrates, and this intermittent current flowing to earth at the distant station, is made to elicit a corresponding note from the receiving apparatus there.

The receiving instruments are of two kinds, electro-magnetic and physiological.

In the first there is a plain double electro-magnet with a steel tongue having one end rigidly fixed to one pole, the other end being free to vibrate under the other pole. This stands over a wooden pipe closed at one end. Thus in Fig. 2 t T is the steel tongue fixed at t and free at

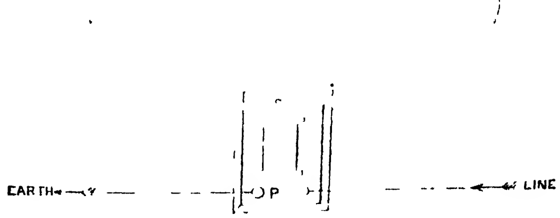

Fig. 3.

T, while P is the sounding-pipe. The received current, coming from the line and passing through the electro-magnet M to earth, sets the tongue vibrating, and the pipe gives forth the same note as the reed at the sending station. Ten Daniell cells working through 1,000 ohms, give a good strong note, especially when the receiver is

held in the hand close to the head. The screw *a*, Fig. 1, must be adjusted to give the best effect.

The other receiving instrument is the most interesting of the two. It consists of a small induction coil used in conjunction with a peculiar sounding-box, as shown in Fig. 3.

Here the line-current is passed to earth through the primary circuit P of the small induction coil, and the induced current is led to the sounding-box. This consists of a flat hollow cylindrical wooden box B, covered by a convoluted face of sheet zinc with two air holes *hh*, perforated in it, this box is attached to a metal axle A, turning in forked iron bearings, insulated from but supported by an iron stand S. By this means the sounding-box can be revolved by the ebony handle E. The zinc face is connected across the empty interior of the box by a wire W to the metal bearings on the other side. One end of the secondary circuit of the induction coil is to be connected to the metal bearing by the terminal *a*, and the other to a short bare wire held in the left hand. On then striking a finger of the hand holding the wire smartly across the zinc face, the proper note is sounded by the box; or, what is more convenient, on turning the box by the insulated handle and keeping the point of the finger rubbing on its face, the note is heard. The rough under side of the finger pressed pretty hard on the bulging part of the face is best. The instant the current is put on by the sending key K, Fig. 1, the dry rasp of the skin on the zinc-surface becomes changed into a musical note.

These "sounders" can be made to receive indifferently a variety of notes. I have under my care at present a telephone with four transmitters tuned to give the four notes of the common chord, and two receivers, which interpret equally well any one of these notes or all together. But sounders are also made in the same way which will emit only one special note, and so are sensible only to the corresponding current. It is by their means that the telephone can be applied to multiplex telegraphy. As many as eight transmitters may be set to interrupt the line current according to the vibrations of eight different tuning-forks, and the resultant current can be made by means of eight special receivers to reproduce the same number of corresponding notes at the distant station. The current is controlled by eight keys at the sending end and sifted by eight sounders at the receiving end, each sounder being sensitive only to those portions of the current affected by its corresponding transmitter. The superimposed effect of the eight keys and transmitters on the line current can all be separately interpreted at the receiving end. Thus eight messages might be transmitted simultaneously along one wire in the same direction. It would seem hitherto, however, that this method of telegraphy by the telephone is inferior to the ordinary methods in point of speed of signalling, and in the length of circuit which can be worked by a given battery power.

J. MUNRO

OUR PERCEPTION OF THE DIRECTION OF A SOURCE OF SOUND[1]

THE practical facility with which we recognise the situation of a sounding body has always been rather a theoretical difficulty. In the case of sight a special optical apparatus is provided whose function it is to modify the uniform excitation of the retina, which a luminous point, wherever situated, would otherwise produce. The mode of action of the crystalline lens of the eye is well understood, and the use of a lens is precisely the device that would at once occur to the mind of an optician ignorant of physiology. The bundle of rays, which would otherwise distribute themselves over the entire retina, and so give no indication of their origin, are made to converge upon a single point, whose excitation is to us the sign of an external object in a certain definite direction. If the luminous object is moved, the fact is at once recognised by the change in the point of excitation.

There is nothing in the ear corresponding to the crystalline lens of the eye, and this not accidentally, so to speak, but by the very nature of the case. The efficient action of a lens depends upon its diameter being at least many times greater than the wave-length of light, and for the purposes of sight there is no difficulty in satisfying this requirement. The wave-length of the rays by which we see is not much more than a ten-thousandth part of the diameter of the pupil of the eye. But when we pass to the case of sound and the ear the relative magnitudes of the corresponding quantities are altogether different. The waves of sound issuing from a man's mouth are about eight feet long, whereas the diameter of the passage of the ear is quite small, and could not well have been made a large multiple of eight feet. It is evident therefore that it is useless to look for anything corresponding to the crystalline lens of the eye, and that our power of telling the origin of a sound must be explained in some different way.

It has long been conjectured that the explanation turns upon the combined use of both ears; though but little seems to have been done hitherto in the way of bringing this view to the test. The observations and calculations now brought forward are very incomplete, but may perhaps help to clear the ground, and will have served their purpose if they induce others to pursue the subject.

The first experiments were made with the view of finding out with what degree of accuracy the direction of a sound could be determined, and for this it was necessary of course that the observer should have no other material for his judgment than that contemplated.

The observer, stationed with his eyes closed in the middle of a lawn on a still evening, was asked to point with the hand in the direction of voices addressed to him by five or six assistants, who continually shifted their position. It was necessary to have several assistants, since it was found that otherwise their steps could be easily followed. The uniform result was that the direction of a human voice used in anything like a natural manner could be told with certainty from a single word, or even vowel to within a few degrees.

But with other sounds the result was different. If the source was on the right or the left of the observer, its position could be told approximately, but it was uncertain whether, for example, a low whistle was in front or behind. This result led us to try a simple sound, such as that given by a fork mounted on a resonance box. It was soon found that whatever might be the case with a truly simple sound, the observer never failed to detect the situation of the fork by the noises accompanying its excitation, whether this was done by striking or by a violin bow. It was therefore necessary to arrange the experiment differently. Two assistants at equal distances and in opposite directions were provided with similar forks and resonators. At a signal given by a fourth, *both* forks were struck, but only *one* was held over its resonator, and the observer was asked to say, without moving his head, which he heard. When the observer was so turned that one fork was immediately in front and the other immediately behind, it was impossible for him to tell which fork was sounding, and if asked to say one or the other, felt that he was only guessing. But on turning a quarter round, so as to have one fork on his right and the other on his left, he could tell without fail, and with full confidence in being correct.

The possibility of distinguishing a voice in front from a voice behind would thus appear to depend on the compound character of the sound in a way that it is not easy to understand, and for which the second ear would be of no advantage. But even in the case of a lateral sound

[1] Abstract of a Communication to the Musical Association, by Lord Rayleigh, F.R.S.

[the] matter is not free from difficulty, for the difference of [int]ensity with which a lateral sound is perceived by the two [ea]rs is not great. The experiment may easily be tried [ro]ughly by stopping one ear with the hand, and turning [ro]und backwards and forwards while listening to a sound [he]ld steadily. Calculation shows, moreover, that the [hu]man head, considered as an obstacle to the waves of [so]und, is scarcely big enough in relation to the wave-[le]ngth to give a sensible shadow. To throw light on this [su]bject I have calculated the intensity of sound due to a [d]istant source at the various points on the surface of a [fi]xed spherical obstacle. The result depends on the ratio [(a]) between the circumference of the sphere and the [l]ength of the wave. If we call the point on the spherical surface nearest to the source the anterior pole, and the opposite point (where the shadow might be expected to be most intense) the posterior pole, the results on three suppositions as to the relative magnitudes of the sphere and wave-length are given in the following table:—

			Intensity.
a	2	Anterior pole	·690
		Posterior pole	·318
		Equator	·356
a	1	Anterior pole	·503
		Posterior pole	·285
		Equator	·237
a	½	Anterior pole . .	·294
		Posterior pole .	·260
		Equator .. .	·232

When, for example, the circumference of the sphere is but half the wave-length, the intensity at the posterior pole is only about a tenth part less than at the anterior pole, while the intensity is least of all in a lateral direction. When a is less than ½, the difference of the intensities at the two poles is still less important, amounting to about one per cent. when $a = \frac{1}{4}$.

The value of a depends on the wave-length, which may vary within pretty wide limits, and it might be expected that the facility of distinguishing a lateral sound would diminish when the sound is grave. Experiments were accordingly tried with forks of a frequency of 128, but no greater difficulty was experienced than with forks of a frequency of 256, except such as might be attributed to the inferior loudness of the former. According to calculation the difference of intensity would here be too small to account for the power of discrimination.

PROF. HUXLEY'S LECTURES ON THE EVIDENCE AS TO THE ORIGIN OF EXISTING VERTEBRATE ANIMALS[1]

VI.

IN the highest group of Vertebrates, the Mammalia, the perfection of animal structure is attained. It will hardly be necessary, indeed it will be impossible, in the time at our disposal, to give the general characters of the group, but our purpose will be answered as well by devoting a short time to considering the peculiarities of a single well-known animal, the evidence as to the origin of which approaches precision.

The horse is one of the most specialised and peculiar of animals, its whole structure being so modified as to make it the most perfect living locomotive engine which it is possible to imagine. The chief points in which its structure is modified to bring about this specialisation, and in which, therefore, it differs most markedly from other mammals, we must now consider.

In the skull the orbit is completely closed behind by bone, a character found only in the most modified mammals. The teeth have a very peculiar character. There are, first of all, in the front part of each jaw, six long curved incisors or cutting teeth, which present a singular dark mark on their biting surfaces, caused by the filling in of a deep groove on the crown of each tooth, by the substances on which the animal feeds. After the incisors, comes on both sides of each jaw a considerable toothless interval, or *diastema*, and then six large grinding teeth, or molars and pr[e]molars. In the young horse a small extra premolar is found to exist at the hinder end of the diastema, so that there are, in reality, seven grinders on each side above and below; furthermore, the male horse has a tusk-like tooth, or canine, in the front part of the diastema immediately following the last incisor. Thus, the horse has, on each side of each jaw, three incisors, one canine, and seven grinders, making a total of forty-four teeth.

The grinding surfaces of the molars and premolars are very curious. In the upper jaw, each tooth is marked by four crescentic elevations, concave externally, the inner pair having each a curious folded mass connected with it. These projecting marks are formed of dentine and enamel, and, consequently, wear away more slowly than the intervening portions of the tooth, which are composed of cement. The lower grinders are marked with two crescents and two accessory masses, but the crescents are convex externally, and, consequently, when the opposite teeth bite together, the elevations do not correspond at any point. In this way a very perfect grinding surface is obtained. The teeth are of great length, and go on growing for a long time, only forming roots in old animals. All these points contribute to the perfection of the horse as a machine, by rendering the mastication of the food, and its consequent prepara[t]ion for digestion in the stomach, as rapid and complete a process as possible.

It is, however, in the limbs that the most striking deviation from the typical mammalian structure is seen, the most singular modifications having taken place to produce a set of long, jointed levers, combining great strength with the utmost possible spring and lightness.

The humerus is a comparatively short bone inclined backwards: the radius is stout and strong, but the ulna seems to be reduced to its upper end—the olecranon or elbow; as a matter of fact, however, its distal end is left, fused to the radius, but the middle part has entirely disappeared: the carpus or wrist—the so-called "knee" of the horse—is followed by a long "cannon bone," attached to the sides of which are two small "splint bones": the three together evidently represent the metacarpus, and it can be readily shown that the great cannon-bone is the metacarpal of the third finger, the splint-bones those of the second and fourth. The splint-bones taper away at their lower ends and have no phalanges attached to them, but the cannon-bone is followed by the usual three phalanges, the last of which, the "coffin-bone," is ensheathed by the great nail or hoof.

The femur, like the humerus, is a short bone, but is directed forwards; the tibia turns backwards, and has the upper end of the rudimentary fibula attached to its outer angle. The latter bone, like the ulna, has disappeared altogether as to its middle portion, and its distal end is firmly united to the tibia. The foot has the same structure as the corresponding part in the fore limb: a great cannon-bone, the third metatarsal; two splints, the second and fourth: and the three phalanges of the third digit, the last of which bears a hoof.

Thus, in both fore and hind limb one toe is selected, becomes greatly modified and enlarged at the expense of the others, and forms a great lever, which, in combination with the levers constituted by the upper and middle divisions of the limb, forms a sort of double C-spring arrangement, and thus gives to the horse its wonderful galloping power.

In the river-beds of the Quaternary age—a time when England formed part of the Continent of Europe—

[1] A course of six lectures to working men, delivered in the theatre of the Royal School of Mines. Lecture VI., April 3. Continued from vol. xiii. p. 516.

abundant remains of horses are found, which horses resembled altogether our own species, or perhaps are still more nearly allied to the wild ass. The same is the case in America, where the species was very abundant in the Quaternary epoch—a curious fact, as, when first discovered by Europeans, there was not a horse from one end of the vast continent to the other.

In the Pliocene and older Miocene, both of Europe and America, are found a number of horse-like animals, resembling the existing horse in the pattern and number of the teeth, but differing in other particulars, especially the structure of the limbs. They belong to the genera *Protohippus*, *Hipparion*, &c., and are the immediate predecessors of the Quaternary horses.

In these animals the bones of the fore-arm are essentially like those of the horse, but the ulna is stouter and larger, can be traced from one end to the other, and, although firmly united to the radius, was not ankylosed with it. The same is true, though to a less marked extent, of the fibula.

But the most curious change is to be found in the toes. The third toe though still by far the largest, is proportionally smaller than in the horse, and each of the splint bones bears its own proper number of phalanges; a pair of "dew-claws," like those of the reindeer, being thus formed, one on either side of the great central toe. These accessory toes, however, by no means reached the ground, and could have been of no possible use, except in progression through marshes.

The teeth are quite like those of the existing horse, as to pattern, number, presence of cement, &c.; the orbit also is complete, but there is a curious depression on the face-bones, just beneath the orbit, a rudiment of which is, however, found in some of the older horses.

On passing to the older Miocene, we find an animal, known as *Anchitherium*, which bears, in many respects, a close resemblance to Hipparion, but is shorter-legged, stouter-bodied, and altogether more awkward in appearance. Its skull exhibits the depression mentioned as existing in Hipparion, but the orbit is incomplete behind, thus deviating from the specialised structure found in the horse, and approaching nearer to an ordinary typical mammal. The same is the case with the teeth, which are short and formed roots at an early period; their pattern also is simplified, although all the essential features are still retained. The valleys between the various ridges are not filled up with cement, and the little anterior premolar of the horse has become as large as the other grinders, so that the whole forty-four teeth of the typical mammalian dentition are well developed. The diastema is still present between the canines and the anterior grinding teeth—a curious fact in relation to the theory that the corresponding space in the horse was specially constructed for the insertion of the bit; for, if the Miocene men were in the habit of riding the Anchitherium, they were probably able to hold on so well with their hind legs as to be in no need of a bit.

The fibula is a complete bone, though still ankylosed below to the tibia; the ulna also is far stouter and more distinct than in Hipparion. In both fore and hind foot the middle toe is smaller, in relation to the size of the animal, than in either the horse or the Hipparion, and the second and fourth toes, though still smaller than the third, are so large that they must have reached the ground in walking. Thus, it is only necessary for the second and fourth toes, and the ulna and fibula to get smaller and smaller for the limb of Anchitherium to be converted into that of Hipparion, and this again into that of the horse.

Up to the year 1870 this was all the evidence we had about the matter, except for the fact that a species of *Palæotherium* from the older Eocene was, in many respects, so horse-like, having, however, well-developed ulna and fibula, and the second and fourth toes larger than in Anchitherium, that it had every appearance of being the original stock of the horse. But within the last six years some remarkable discoveries in central and western North America, have brought to light forms which are, probably, nearer the direct line of descent than any we have hitherto known.

In the Eocene rocks of these localities, a horse-like animal has been found, with three toes, like those of Anchitherium, but having, in addition, a little style of bone on the outer side of the fore foot, evidently representing the fifth digit. This is the little *Orohippus*, the lowest member of the Equine series.

This evidence is conclusive as far as the fact of evolution is concerned, for it is preposterous to assume that each member of this perfect series of forms has been specially created; and if it can be proved—as the facts adduced above certainly do prove—that a complicated animal like the horse may have arisen by gradual modification of a lower and less specialised form, there is surely no reason to think that other animals have arisen in a different way.

This case, moreover, is not isolated. Every new investigation into the Tertiary mammalian fauna brings fresh evidence, tending to show how the rhinoceros, the pigs, the ruminants, have come about. Similar light is being thrown on the origin of the carnivora, and also, in a less degree, on that of all the other groups of mammals.

It may well be asked why such clear evidence should be obtainable as to the origin of mammals, while in the case of many other groups—fish, for instance—all the evidence seems to point the other way. This question cannot be satisfactorily answered at present, but the fact is probably connected with the great uniformity of the conditions to which the lower animals are exposed, for it is invariably the case that the higher the position of any given animal in the scale of being, the more complex are the conditions acting on it.

It is not, however, to be expected that there should be, as yet, an answer to every difficulty, for we are only just beginning the study of biological facts from the evolutionary point of view. Still, when we look back twenty years to the publication of the "Origin of Species," we are filled with astonishment at the progress of our knowledge, and especially at the immense strides it has made in the region of palæontological research. The accurate information obtained in this department of science has put the *fact* of evolution beyond a doubt; formerly, the great reproach to the theory was, that no support was lent to it by the geological history of living things; now whatever happens, the fact remains that the hypothesis is founded on the firm basis of palæontological evidence.

THE LOAN COLLECTION CONFERENCES

CONSIDERABLE progress has been made in the arrangements for holding conferences in connection with the approaching Loan Collection of Scientific Apparatus at South Kensington.

In the Section of Mechanics, which includes Pure and Applied Mathematics and Measurement, the conferences will be held on May 17, 22, and 2[illegible], and the following gentlemen have promised to give addresses or to take part:—

Dr. Siemens, F.R.S., general address with special reference to Measurement.

Mr. F. J. Bramwell, F.R.S., on Prime Movers.

Mr. Barnaby, Director of Naval Construction to the Admiralty.—Naval Architecture.

Mr. W. Froude, M.A., F.R.S.—Fluid Resistance.

M. Tresca, Sous-Directeur du Conservatoire des Arts et Métiers, Paris.—Flow of Solids.

M. le General Morin, Directeur du Conservatoire des Arts et Métiers, Paris.—Ventilation of Public Buildings.

Sir Joseph Whitworth, Bart., F.R.S.—Linear Measure-

Prof. Goodeve, M.A.—Solid Measurement.
Prof. Kennedy, C.E.—Kinematics.
Mr. W. Hackney.—Furnaces.
Prof. Sir W. Thomson, LL.D., F.R.S.—Electrical Measurement.
Mr. Westmacott.—Hydraulic Transmission.
Prof. Tilser (Bohemian Polytechnic Institute, Prague).—His new Method of Descriptive Geometry.

In the Section of Physics (including Astronomy), the following arrangements have been made provisionally:—

May 16.—Address by the President, Mr. Spottiswoode; Mr. Norman Lockyer, Capt. Abney, and Mr. Huggins—Spectroscopy; Prof. Clifton—Interference; Professors Adams and Stokes, and Mr. Spottiswoode—Polarisation; Mr. Sorby, or Dr. Royston Pigott—Microscopes; M. Becquerel and Prof. Stokes—Fluorescence; Sir W. Thomson—Electrometers.

May 19.—Prof. Tyndall—Reflection of Sound; Prof. Adams—Wheatstone's Researches; Prof. Guthrie—Heat; Mr. De la Rue—Astronomical Photography; and M. Leverrier.

May 24. Prof. Clerk-Maxwell, Prof. Andrews, and M. Tresca—Molecular Construction of Matter; Mr. De la Rue—Electric Batteries; Prof. Carey Foster—Galvanometers; Baron Ferdinand von Wrangel—Voltameters; M. Viandel—Gramme's Machine; and M. Helmholtz.

The conferences in Chemistry will be held on the 18th and 23rd May, and the following communications have been promised:—

Address by the Chairman, Dr. Frankland, F.R.S., generally on the objects exhibited in this section, and specially on the instruments used for the investigation of gases.

Dr. J. H. Gilbert, F.R.S., on some points in connection with vegetation.

Mr. Donkin, Demonstrator of Chemistry in the Oxford Museum, on Sir B. Brodie's apparatus used in the investigation of ozone.

M. Fremy, Membre de l'Institut de France, on the preservation of animal food.

Prof. Roscoe, F.R.S., on Vanadium and its compounds.

Prof. Guthrie, F.R.S., on Cryohydrates.

The conferences in Biology will be held on May 26 and 29, and will relate chiefly to the following subjects, viz.:—

(1) The methods of measurement and registration which are applicable to the vital phenomena of plants, animals, and man; (2) the methods and instruments employed in physiological optics and acoustics; and (3) the modes of preparing the tissues of plants and animals for microscopical examination. Explanations of apparatus and instruments will be given by the President, Professors Donders, Hering, Marey, Crum Brown, M. Foster, Flower, M'Kendrick, Thiselton Dyer, Messrs. Liebreich, Pritchard, Mosso, Gaskell, and others.

The Conferences in Physical Geography, Geology, Mineralogy, and Meteorology will be held on May 30, and June 1 and 2, and the following gentlemen have promised to take part:—

Mr. John Evans, F.R.S., general address on the objects exhibited in the section. In Meteorology, Prof. Roscoe, Mr. T. Stevenson, Mr. R. H. Scott, Mr. G. J. Symons, Dr. Mann, and Mr. Galloway. In Geography, Major Anderson, Lieut. Cameron, Mr. Clements Markham, Col. Walker, Professeur Forel, Prof. Wyville Thomson, and Mr. Francis Galton. In Geology and Mining, M. Daubrée, Prof. Ramsay, Mr. Rance, Baron Von Ettinghausen, and Mr. Topley. In Mineralogy, &c., M. des Cloiseaux, and the Rev. N. Brady.

NOTES

The Eighth Annual Report of the Geological and Geographical Survey of the Territories, under the direction of Prof. F. V. Hayden, has just been issued from the U.S. Government Printing Office. It is a report of progress of the explorations, mainly in Colorado, for the year 1874, and contains twelve articles in 500 octavo pages, and eighty-eight illustrations, including maps and sections. It commences with an introductory letter to the Secretary of the Interior, under whose auspices the survey is conducted, which contains a general account of the organisation of the various field divisions, and the progress of the work. Following this is the part devoted to geology, mineralogy, and mining industry, containing the reports of Prof. Hayden, Wm. H. Holmes, Dr. A. C. Peale, Dr. F. M. Endlich, and Samuel Aughey, Ph.D. Dr. Hayden's report is devoted to the special geology of the eastern part of the Rocky Mountains in Colorado, the Arkansas Valley, and portions of the Elk Mountains. The report of Wm. H. Holmes is devoted to the geology of the north-western portion of the Elk Mountains. The report of Dr. A. C. Peale gives the general and special features of the district assigned to the middle division of the survey, viz., the country lying between the Grand and Gunnison rivers west of the 107th meridian. Dr. F. M. Endlich reports on the San Juan country, giving chapters on the metamorphic, volcanic, and sedimentary areas and mines of the region. All these reports are abundantly illustrated with woodcuts, sections, and geological maps. Dr. Samuel Aughey has an interesting and practical report on the superficial deposits in Nebraska. The second paper is devoted to palæontology, and contains papers on the flora of the lignitic formations of North America, by Mr. Leo Lesquereux. A large number of new fossil plants are described and illustrated in eight plates. Following the palæontology is the report of Mr. W. H. Jackson on the ancient ruins of South-western Colorado. Eight plates of the cliff-houses, cave-dwellings, and other ruins of the Mancos, McElmo, and Hovenweep rivers accompany the report. Following Mr. Jackson's interesting report is an article on the zoological work for 1874. It contains descriptions and figures of several new species in conchology. The last division of the volume comprises the portion devoted to topography and geography, containing the following reports:—Mr. Henry Gannett's on the middle district, Mr. S. B. Ladd's on the northern district, and Mr. A. D. Wilson's and Franklin Rhoda's on the San Juan or southern district. These reports give the general topographical features of the areas surveyed, the means of communication and elevations of principal points. A complete table of contents and exhaustive indexes accompany the report. There is a general index of systematic names.

Orders have been given by the French Minister of Public Works for entering into a contract for the construction of the large refractor, whose length will be seventeen metres. A sum of 210,000 francs is to be paid to M. Eichens when the work is completed. The huge instrument is to be delivered two years hence. It will not be placed under a movable shade like the great reflector, but a cupola of requisite dimensions is to be constructed. All these arrangements have already been devised by M. Leverrier.

In a lecture on the Geographical Distribution of Birds, the first of a course delivered by Mr. R. B. Sharpe, on the 2nd inst., at the St. John's Wood Assembly Rooms, the lecturer exhibited, by the oxycalcium light, a large series of maps of the world, about fifty in number, each coloured in that part only where the bird he was speaking of is distributed. A carefully-painted slide of the bird, from the pencil of Mr. Keulemans, was also introduced with the description of the plumage of each species, and in association with the map of its distribution.

A plague of Field Voles (*Arvonicola agrestis*) has recently visited some of the pastoral farms of Upper Teviotdale and the adjoining districts, which has led to the appointment of a committee of the Farmers' Club of the Locality for the purpose of

estimating the amount of the damage done. This was found to be very considerable, the vermin eating the pale and succulent bases of the grass, as well as the young shoots. No great destruction of other vermin has occurred in the district, so it cannot be said that the Voles have become particularly abundant from that cause. Similar plagues have before now occurred in the New Forest.

A SCIENTIFIC Society and Field Club has been formed in the northern burgh of Inverness. We have received the inaugural address of the President, Mr. William Jolly, on "The Scientific Materials of the North and our Scientific Work." Mr. Jolly has lofty ideas of what the work and influence of such a society should be, and we hope his address will have a stirring effect upon the members. Inverness is a fine centre for a field-club, especially in the region of geology. We are also glad to see that a Monmouthshire Geological Society has just been formed; its first general meeting was held on the 2nd inst.

THE *Geographical Magazine* for May contains an article on the prospects for the Arctic Campaign of 1876. While we must be prepared for the necessity of the ships spending a second winter in the north, the writer thinks that possibly the *Pandora*, which goes out this month for news and letters, may meet them coming out of Smith Sound, "with their work done, their great enterprise completed." There is also an article, with map, on the Island of Socotra, which the British Government have arranged to occupy, and another by M. Venyukof on New Maps of Mongolia.

THE Supplementary Part, 46, of *Petermann's Mittheilungen* consists of a valuable memoir on the Pekin Plain and the neighbouring Mountain-land, by Dr. Bretschneider, Physician to the Russian Embassy at Pekin. It is accompanied by a map of Pekin and the district around.

AT the Royal Geographical Society on Monday the following papers were read:—"The Country and Natives of Port Moresby, New Guinea," by Mr. O. C. Stone, and "The Natives and Products of Fly River, New Guinea," by Signor L. M. D'Albertis. Mr. Stone's paper gave some details of the country and the people, speaking, on the whole, well of the latter. Signor D'Albertis's paper gave somewhat similer details as to the country in the neighbourhood of the Fly River. Dr. Mullens read a few notes, in which he described the details of his excursions in different parts of Central New Guinea. Sir Henry Rawlinson hoped a "Cameron" for New Guinea would soon turn up, and that Mr. Young would be the coming explorer, and would force himself into the large and comparatively unknown regions of New Guinea.

LETTERS from Sydney, dated March 17, inform us that the Governor of New South Wales has provided M. D'Albertis with a steam-launch for the exploration of the Fly River, and that he was intending to return to New Guinea ten days later. A public meeting was to be called at Sydney to provide for M. D'Albertis's other expenses in connection with the expedition.

AT the Crystal Palace Aquarium the hatching of the spawn of Axolotls has been successfully accomplished. There are three young "broods," and some still unhatched spawn, so that the changes in growth during the first few weeks can be seen all together.

WE greatly regret to learn that the Massachusetts House of Representatives have by a majority refused to entertain at present any proposal for a new and much-needed survey of that state. We referred to the matter about a year ago, when everything promised well (vol. xi. pp. 381, 497). We can only hope that the present unpatriotic mood of the Legislature will not last long.

ON Monday and Tuesday-week the first Annual Meeting of the Cumberland Association for the Advancement of Literature and Science was held at Whitehaven, when an instructive inaugural address was given by the Bishop of Carlisle, the President of the Association. Other interesting papers were read and excursions made, including a geological excursion along the coast under the guidance of Mr. J. C. Ward, and others. Accounts of some of the confederated societies were given, and altogether this first meeting of the Association promises well for its future and for the cause of culture in Cumberland.

THE Cape of Good Hope University has decided to throw open unreservedly degrees, honours, and pecuniary emoluments at the disposal of that body to candidates who desire to be examined in places beyond the bounds of the Cape Colony, provided the Government of the Colony or the State in which such candidates reside shall be annual contributors of 200*l*. to the funds of the University.

DR. M. T. MASTERS has been experimenting on the functions of the nectaries formed by the small cup-shaped petals of *Helleborus*, and finds that they absorb or digest nitrogenous substances, repeating in all respects the phenomena of the leaves of *Drosera* and *Dionæa*.

WE have received from Prof. Sachs a reply to Reinke's series of papers "Untersuchungen uber Wachsthum" in the "Botanische Zeitung" challenging the correctness of experiments made in Prof. Sachs's laboratory at Würzburg on the rate of growth of plants; also a lecture on the "Nourishment of Plants," giving a popular account of the state of our knowledge respecting the phenomena of plant-life.

M. VOGEL, of Munich, has observed, says the *Belgique Horticole*, that seeds germinate much more quickly when watered with water containing camphor than with pure water.

THE Rev. S. J. Perry, F.R.S., has reprinted, in a separate form, his "Notes of a Voyage to Kerguelen Island to observe the Transit of Venus," from the *Month*. These Notes refer not only to the immediate object of the expedition, but describe in a pleasant way the voyage out and the nature of the desolate island which was the home of the various expeditions for many weeks. Many, besides astronomers, will find the narrative interesting and instructive. H. S. King and Co., are the publishers.

FROM Prof. O. C. Marsh we have received a paper on the principal characters of the Brontotheridæ (Titanotheridæ of Flower, NATURE, vol. xiii. p. 327), in which several additions are made to our knowledge of the group. Four genera are described, differing in the number of the always feebly developed incisor teeth. The brain-case is shown to have been small. The toes were the same in number as in the existing Tapirs, four in front and three behind. All the known remains of these animals are from east of the Rocky Mountains, in the Miocene beds of Dakota, Nebraska, Wyoming, and Colorado. Figures of the skull, teeth, brain cavity, and feet, accompany the description.

THE additions to the Zoological Society's Gardens during the past week include three Brown Howlers (*Mycetes fuscus*) from New Granada, a Brazilian Tree Porcupine (*Cercolabes prehensilis*) from South America, deposited; two Leopards (juv.) (*F... pardus*) from India, presented by Mr. Ge... W.I. Regiment; a Grey Ichneum... (*Herpestes griseus*) from India, presented by ... W. H. Worth; five Water Ouzels (*Cinclus aquaticus*), European, presented by Mr. Frederick Swabey ... a Black-headed Gull (*Larus ridibundus*), a Herring Gull ... (*Larus argentatus*), European, presented by Mr. Brazenor; a C... Collection of Marine Fishes from the British Seas, presented by Dr. A. H. Smee; five Common Rabbits (*Lepus cuniculus*) European, deposited by Master B. Sclater; a Hoffmann's Sloth (*Cholopus hoffmanni*) from Panama, purchased; twenty Land Crabs from the Ascension, presented by Mr. Wm Drew.

SCIENTIFIC SERIALS

THE *Quarterly Journal of Microscopical Science* contains several papers of importance. The first is by Dr. Klein, entitled "Observations on the Early Development of the Common Trout (*Salmo fario*)," in which the condition of the blastoderm between the third and thirteenth day is described. The subject is minutely treated, and the bibliography is very complete.—Mr. John Priestley gives a *résumé* of recent researches on the nuclei of animal and vegetable cells, and especially of ova, and afterwards collates the various statements, indicating their points of divergence.—The investigations of Prof. E. Auerbach and Strasburger, of Dr. Oscar Hertwig and Van Beneden, are those discussed.—M. Edouard Van Beneden's valuable "Contributions to the History of the Germinal Vesicle, and of the first Embryonic Nucleus" contains much of special interest with reference to the relation of the germinal vesicle and the first cleavage nucleus of the egg, especially with reference to the different results arrived at by the author in his study of the ovum of the rabbit, and M. Hertwig's investigations on the echinoderm *Toxopneustes lividus*.—Mr. H. R. Octavius Sankey gives a new method for examining the structure of the brain, and reviews some points in the histology of the cerebellum. The dye employed for the staining is aniline blue-black, in which sections of fresh brain should remain twelve hours or so, and afterwards be dried.—Dr. James Foulis gives a lengthy memoir on the development of the ova and structure of the ovary in man and other mammalia. Three plates accompany his paper. The author mainly devotes himself in this communication to the description of the appearances in the ovaries of young kittens, and of the human fœtus, with the object of demonstrating, in particular, that whereas the eggs are derived from the germ epithelium, the nutrient cells of the ovum, or the follicular epithelial cells, are derived from the cells of the stroma of the ovary.—Dr. Carpenter, in a paper on the genus *Astrorhiza* of Sandahl, lately described as *Haeckelina*, by Dr. Bessels, reintroduces the earlier account of the genus, and figures it.

Journal of Botany.—Among the more important articles on descriptive and systematic botany in this periodical since the commencement of the current year are a description of *Rumex rupestris*, Le Gall, as a British plant, by Dr. Trimen, with a plate: a description of four new species of Fuchsia from South America, by Mr. Hemsley, and a conspectus of the genus *Glycosmis*, by Mr. Kurz, with two plates. Mr. Sorby contributes a paper on the colouring matter associated with chlorophyll, in which he combats some of the conclusions of Pringsheim, and Prof. Church some further notes on plant-chemistry, with analyses of *Lactuca sativa*, *Chondrus crispus*, in which the ash reaches the very large amount of 14·15 per cent. of the air-dry plant, and *Nasturtium officinale*, and of the ash of the bud-scales of the beech, and of the female flowers of the elm. In the April number is the commencement of Prof. De Bary's very important report of researches into the nature of the potato-fungus, *Phytophthora infestans*.

Although the articles in the *Scottish Naturalist* are mainly of local interest, two notable exceptions are furnished by those on "Animal Psychosis," by the Rev. J. Wardrop, and "Illustrations of Animal Reason," by Dr. Lauder Lindsay, portions of which occur in the numbers for January and April, both of which we hope to see reprinted in a form to reach a larger public. There are a large number of notes on the zoology of Scotland, and Mr. A. Sturrock records an addition to the flora of that country in the discovery, in Loch Cluny, Perthshire, of *Naias flexilis*, hitherto confined to Ireland as far as the British Islands are concerned. Dr. Buchanan White and Dr. Sharp continue their lists of the Lepidoptera and Coleoptera of Scotland respectively.

Poggendorff's Annalen der Physik und Chemie, No. 1, 1876. —In Regnault's experiments on the specific heat of gases, it was necessary that the spiral through which the gas streamed should have considerable length, so that the gas might fully take the temperature of the heating vessel, and fully yield up its heat in the calorimeter. A correspondingly large size of vessel and a large quantity of gas were required. In a new investigation by E. Wiedemann, here described, the chief object was to diminish the calorimeter, and yet not compromise the yield of heat of the gas, that is, to afford the heated gas as great a surface in as small a space as possible. His heating vessel was a copper cylinder stuffed with copper turnings and enclosed in another copper vessel containing water or paraffin to be heated. In the calorimeter the gas passed successively through three vertical and connected silver pipes filled with silver turnings, and gave its heat to the surrounding liquid. The author shows that his method is not behind that of Regnault in accuracy, and as the quantity of water was only a tenth of that which Regnault used, only a tenth part of the gas was required, to obtain as great elevation of temperature. Thus extensive results could be had in shorter time. The tabulated numbers for the seven gases examined do not materially differ from those of Regnault.—A paper by Dr. Dvorak follows, describing many interesting experiments on acoustic attraction and repulsion. He studies the case of rods in transverse vibration; also the action of a screen in a sound wave; acoustic attraction and repulsion of resonance; also that in liquids and the phenomena in air columns thrown into continuous vibrations.—The observations of M. Plateau on liquid films are extended by Dr. Sondhauss, who endeavoured to determine the extent to which different liquids could be stretched in films in wire rings, observed such lamellæ in closed vessels excluding external disturbances, measured with a balance their tension, and, with a manometer, the pressure of bubbles on the enclosed air; he also measured the weight of such lamellæ and bubbles, whence their thickness might be inferred. With a simple contrivance, consisting of a thin wire bent horizontally to an angle and a straight wire placed across and drawn gradually away from the angle, it may be shown that all liquids can be stretched in lamellæ, and different liquids may be compared in this respect. But Dr. Sondhauss prefers the circular wire rings. He compares (as to size) the films got from forty-six different liquids. Among some facts relating to durability of films, we note that one film from a quillaja decoction, to which a little glycerine had been added, was produced in a vessel on 1st Sept., 1872, and lasted till 11th March, 1873, or over half a year.—M. Groth communicates the results of a study of the elasticity of rock salt by observation of the velocity of sound in different directions in it, a method more easily carried out than that of M. Voigt, who measured the elastic bending of rods of the substance. The researches of both leave no doubt that in regular crystals the coefficient of elasticity, and therewith the velocity of sound, is a function of the direction; and in accordance with Neumann's theory, they vary symmetrically with reference to the planes of symmetry of the crystal. A geometrical plane of symmetry of a crystal is at the same time a physical plane of symmetry. A crystal may be defined as a homogeneous solid body whose elasticity varies with the direction.—We further note the first part of a valuable paper by M. Grotrian, on the constants of friction of some salt solutions and their relations to galvanic conductivity; and some observations of M. Edlund on the connection of galvanic induction with electro-dynamic phenomena; also, extracted papers on the occurrence of nitrogenous iron among the fumarole products of Mount Etna, and on the thermo-electric properties of some calcareous spar, beryll, idocrase, and apophyllite.

Revue des Sciences Naturelles, December, 1875.—The most interesting original observations recorded in this number are contained in a short paper by D. A. Godron, on fertilisation of flowers by Hymenoptera. Near Nancy it is found that the hybrid produced by the fertilisation of *Primula grandiflora* with pollen of *P. officinalis* results from the intervention of bees, but the converse hybrid does not occur. M. Godron published an account of this in 1844. The reason for the non-occurrence of the second hybrid is that *P. grandiflora* flowers earlier in this locality than *P. officinalis*. M. Godron was able to produce the hybrid *P. grandiflora-officinalis* artificially, but never saw it as a natural product till March, 1874, when it was brought to him from a locality two kilometres distant from the first. On investigation it was found that only *P. officinalis* grew at this spot, and that owing to situation and surroundings it flowered much earlier than in the other locality; but the hybridisation could only be effected by the carrying of the pollen of *P. grandiflora* two kilometres by bees.—The summaries of French memoirs on science are full and valuable; foreign summaries of moderate extent are likewise given.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, May 4.—"On the Absorption-Spectra of Bromine and Iodine Monochloride," by H. E. Roscoe, F.R.S., and T. E. Thorpe.

The paper contains the results of an exact series of measurements of the absorption-spectra of the vapours of the element bromine and of the compound iodine monochloride, made with the object of ascertaining whether the molecules of these two gases vibrate identically or similarly, their molecular weights and colour of the vapours being almost identical.

A careful comparison of these Tables and of the map shows that, although both spectra contain a large number of lines which are nearly coincident, the spectra as a whole are not identical, either when the vapours are examined at high or low temperatures, or when the length of the columns of absorbing gas are varied.

Linnean Society, April 20.—G. Bentham, F.R.S., vice-president, in the chair.—Mr. Hudson, Dr. Prior, Mr. Stainton, and Mr. C. Stewart were appointed auditors for the current year.—Dr. Hooker, P.R.S., exhibited some specimens illustrating a communication from Dr. J. Kirk, which was read. This latter referred to the identification of the modern copal tree, *Trachylobium Hornemannianum*, with that which yielded the Zanzibar Copal or Gum Animi, now found in the earth on the east coast of Africa, and often where no copal yielding tree now exists. Little doubt now rests as to the identity of the semi-fossil with the living tree, inasmuch as bijugate leaf, flower-bud, flower, ovary and stamens, characteristic of the latter have been discovered in the so-called Animi. Dr. Kirk is inclined to account for their difference in quality by a molecular or chemical change in the buried material; improving it thereby, and as a consequence increasing its market value.—Mr. W. P. Hiern read a paper "On the African species of the genus *Coffea*, Linn." As at present understood this genus belongs to the Old World, and the numerous American species that have previously been referred to it, now find places in other genera. All the species most valuable for economic or commercial purposes are confined to Africa or are of African origin. Of the seven Indian species, one formerly was cultivated, but from its inferiority has since been discarded in favour of the African plants. The so-called wild coffee of Sierra Leone and Fernando Po, and other berries, are occasionally used by the inhabitants of those places as coffee; but they do not belong to the genus in question. The author distinguishes and technically characterises some fifteen species of coffee plant as indigenous to Africa and its adjacent islands. They are:—1. *C. arabica*, 2. *C. liberica*, 3. *C. stenophylla*, 4. *C. zanguebariæ*, 5. *C. brevipes*, 6. *C. melanocarpa*, 7. *C. mauritiana*, 8. *C. Macrocarpa*, 9. *C. hypoglauca*, 10. *C. microcarpa*, 11. *C. afzelii*, 12. *C. subcordata*, 13. *C. rupestris*, 14 *C. jasminoides*, 15 *C. racemosa*. He rejects some six supposed species of African Coffees, showing these belong to other groups. Of the 15 species, 13 inhabit the African Continent, and 2 pertain to Mauritius and Bourbon; so far as yet explored, West Africa furnishes 11 species, and but two are found in East and Central Africa. Mr. Hiern describes numbers 2, 5, 11, 12, and 13, viz., five in all as new species, and three others are MS. names of specimens in the herbarium of the late distinguished botanist, Mr. Welwitsch. He alludes to a pale-berried variety of the *C. arabica* found by Vogel in Sierra Leone. By far the most interesting new plant commercially and otherwise is the Liberian Coffee introduced into this country in 1874, by Mr. W. Bull, the horticulturist. This is said to be far superior to the ordinary coffee of commerce, *C. arabica* having larger berries, a finer flavour, and being at the same time more robust and productive.—A paper "On the Classification of *Narcissus*," by Mr. Shirley Hibberd, was announced.—Mr. Thiselton Dyer read a note "On the Plant yielding Lattakia Tobacco," and exhibited specimens corroborating the conclusions arrived at by him. These latter are that Lattakia tobacco is produced by a different species to the Turkish, and that as imported into this country it consists of the flowering twigs made up into bundles which have been smoked with pine wood.—Prof. Dickie had a summary read of a further contribution of his to the botany of the *Challenger* expedition, viz., a List with Remarks of the Polynesian Algæ collected by Mr. Mosley. Only a very few species appear to be new to science.—Dr. Hooker communicated a paper of P. F. Reinsch's, on New Freshwater Algæ obtained by the Venus Transit Expedition in the Island of Kerguelen. This being technical in character, was taken as read.

Chemical Society, May 4.—Dr. Gilbert, vice-president, in the chair.—Eight communications were made to the Society, namely:—On glycero-phosphoric acid and its salts as obtained from the phosphorised constituents of the brain, by Dr. J. L. W. Thudicum and Mr. C. T. Kingsett.—On some reactions of biliverdin, by Dr. Thudicum.—On the r between chemical constitution and colouring power in a substances, by Dr. O. Witt.—On certain bismuth comp by Mr. M. M. P. Muir.—A new method for preparing hydrocarbons diphenyl and isodinaphthyl and on the ac a high temperature of metallic chlorides on certain hydrocarbons, and a note on the occurrence of benzene in rosin s, both by Mr. W. Smyth.—On the action of water and saline solutions on copper, by Mr. T. Carnelly, and notes on riments made to ascertain the value of a proposed method determining the mineral strength of soils by means of wat culture, by Mr. G. W. Hight.

Zoological Society, May 2.—Robert Hudson, F.R.S., vice-president, in the chair.—Mr. G. Dawson Rowley exhibited and made remarks on a specimen of *Machærirhynchus nigripec* from New Guinea, believed to be the first example of this bird which had reached this country.—Extracts were read from several letters received from Dr. George Bennett, F.Z.S., giving some account of the proceedings of Mr. L. M. D'Albertis, and of his recent expedition up the Fly River in December, 1875.—Mr. J. H. Gurney, jun., exhibited and made remarks on an example of the Lesser White-fronted Goose, from Egypt, being the first record of the occurrence of this species in Africa.—Mr. Osbert Salvin, F.R.S., exhibited and made remarks on a piece of a trunk of a pine from Guatemala, which had been perforated by a Woodpecker (*Melanerpes formicivorus*), for the purpose of storing acorns.—Mr. A. Grote exhibited and made remarks on Col. Gordon's drawing of *Ovis polii*, which was the original of the figure given in the Society's *Proceedings* for 1874.—George Busk, F.R.S., read a memoir on the Ancient or Quaternary Fauna of Gibraltar, as exemplified in the Mammalian remains of the ossiferous breccia, which occurs in the caves and fissures recently explored in different parts of the rock.—Mr. Busk, after a preliminary description of the geological features of the rock and its fossiliferous caverns and fissures, treated specially of the various bones of the bear, cat, horse, rhinoceros, stag, ibex, and other animals, of which the remains occur there, and proceeded to refer them to the species to which they seemed to belong.—Prof. A. H. Garrod read a paper on the anatomy of the Colies (*Colius*), which he regarded as belonging to the Piciform group of the division of Anomalogonatous birds according to his arrangement, but constituting an independent family.—A communication was read from Mr. E. L. Layard, containing the description of a new Blackbird (*Turdus*), from Taviuni, one of the Fiji Islands. The Rev. Canon Tristram read a note on the occurrence of the Roebuck in Palestine.

Geological Society, April 26.—Prof. P. Martin Duncan, F.R.S., president, in the chair.—The Rev. Edwin Hill, M. was elected a Fellow, and Prof. Beyrich, of Berlin, a Fo member of the society. The following communications read: A translation of the notice by Capt. Miaulis of the royal navy, of the occurrence of a submarine crater with Harbour of Karavossera, in the Gulf of Arta. Commun by the Secretary of State for Foreign Affairs.—"The p history of the Dee, Wales," by Prof. A. C. Ramsay. The author stated that he regarded the valley of the mainly preglacial throughout, and sketched the physical h of the region through which it runs. The silurian rocks much disturbed and denuded before and during the Carboniferou period, and the carboniferous limestone was deposited very conformably on the upturned edges of both lower and upper silurian strata, and once spread all over the region, probably overlaid by the millstone grit and coal-measures, as now in the east of Denbighshire and Flintshire. The region was again disturbed and elevated during the formation of the Permian deposits, and then by sub-aerial denudation a great part of the carboniferous series was removed down to the old plain of denudation of the Silurian rocks, the surface of which thus probably stood higher than it does at present, being in the midst of a broad continental area. From a consideration of the conditions of deposition of the Mesozoic and Tertiary formations the author concluded that, from the beginning of the Permian to that of the Glacial epoch, the higher ground of Wales was land well raised above the sea, except perhaps during the deposition of the chalk, and th during all this period it was exposed to the influence of su aerial agents of denudation. He indicated the condition elevation of the old table-land of carboniferous rocks, showed that it had probably a slope towards the east and cast to the extent of about 23 feet in a mile. The drainag this land then flowed in an easterly and north-easterly direc

along the earliest channel of the Dee, which would be at an elevation from 1,300 to 1,400 feet higher than the present channel. During the Glacial epoch ice-action deepened, and more or less modified the existing channel, and scooped out the basin of Bala Lake, which was not previously in existence. The general results of this investigation are as follows:—After the last important disturbance of the pre-Permian rocks, North Wales was carved slowly and by sub-aërial agencies into its present mountainous form, chiefly between Permian and Preglacial times. The work of the glaciers of the latter period somewhat deepened, widened, smoothed, and striated the minor outlines of the mountains and valleys, and excavated many rock-bound lake-basins, but did not effect any great changes in the contours of the country. A minor submergence of part of Britain during part of the Glacial epoch produced no important effects on the large outlines of the rocky scenery; and the effects of sub-aërial waste subsequent to the Glacial epoch have been comparatively small.—On the Ancient Volcano of the District of Schemnitz, Hungary, by Mr. John W. Judd. The old volcanoes of Hungary have long been known to present some very interesting illustrations of the relations between the igneous rocks erupted at the surface, and those which have consolidated at a considerable depth beneath it. The district in which these phenomena can be best studied is that of Schemnitz; but although this area has been very carefully mapped and explored by a number of able investigators, the greatest diversities of opinion still exist concerning the relations of certain of the rock-masses exposed within it. Over an area nearly fifty miles in diameter enormous accumulations of *andesite* and *quartz-andesite* lavas and agglomerates have been erupted, these now forming a group of mountains rising from 3,000 to 4,000 feet above the sea-level, and culminating in a great ring of precipitous heights overlooking a depressed central area of oval form, the site of the famous mining towns of Schemnitz, Kremnitz, and Konigsberg. In the midst of this depressed central area there occurs a considerable development of *rhyolitic* lavas and tuffs, and more scattered outbursts of *basalt*. From the magnificent floras associated with the various volcanic tuffs, we know that the andesitic rocks were erupted during the earlier portion of the Upper Miocene period and the rhyolitic towards its close, while the basalts are probably of as late date as the Pliocene. Besides the rhyolites and basalts, however, there are certain other rocks exposed in the central area of the Schemnitz district, the relations of which it is very difficult to understand. These consist of (1) strata of Lower Trias and Nummulitic age, through the midst of which the volcanic outbursts have evidently taken place; (2) masses of highly metamorphic rocks, including quartzites, crystalline limestones, various schists, gneiss and aplite; and (3) undoubted eruptive rocks, which have usually been called "syenite and granite," but for which the names of "diorite and quartz-diorite" would perhaps be more appropriate, inasmuch as the prevailing felspar in them is always a plagioclase variety. By Beudant and other early writers the andesitic lavas were recognised as volcanic products of a comparatively recent geological period, while the "granite, syenite, and greenstone," were regarded as being of far more ancient date. By von Pettko, Richthofen, and all the more recent investigators of the district, however, it has been clearly perceived that the "greenstones" are certainly, like the andesites, of Tertiary age, and hence such names as "greenstone-trachyte" and "propylite" have been applied to them. The studies of the author of the present memoir, both in the field and in the cabinet, have led him to the conclusion that the granitic, porphyritic, and lava rocks—which were formerly called "syenite," "greenstone," and "trachyte" respectively—*are all of similar composition and equivalent age*, and that they differ only in their more or less perfect state of crystallisation, the result evidently of variations in the conditions under which they have consolidated. He is further led to regard the metamorphic masses, around the several intrusive centres as being not, as has hitherto been maintained, of "Primary" (Devonian or Permian) age, but simply Triassic rocks affected by local or contact metamorphism. The real structure of the great Schemnitz volcano was first recognised by von Pettko in 1848, though this author erroneously regarded it as presenting an example of a "crater of elevation." The history of the formation and destruction of this volcano is now shown to be as follows:—After some small and scattered outbursts of rocks of acid composition towards the close of the Oligocene period, the grand eruptions of andesitic lavas of the Miocene began, through the agency of which a volcano of larger dimensions than Etna was gradually built up, by both central and lateral eruptions. In the midst of this volcano a crater of enormous dimensions was formed, doubtless by some great paroxysmal outbreak, and by the subsequent subsidence of the mountain the sea gained access to, and by denudation greatly enlarged the area of this "Caldera." Then in the central lagoon of the caldera a number of minor eruptions, first of acid and then of basic rocks took place; and the volcano, which at this period of its history must have closely resembled the existing island of Santorin, was again upheaved from beneath the sea, and exposed to the wasting effects of subaerial denudation. The gradual decline of the volcanic forces in the district was marked, as is usually the case, by the appearance of hot and mineral springs, discharges of gas, occasional earthquakes, &c. While affording such remarkable examples of the perfect transition between the so-called plutonic and the volcanic classes of rocks, and of the phenomena of contact metamorphism, the granitic masses of the Schemnitz district are without question truly *intrusive*; and a careful study of them lends no support whatever to the hypothesis that such rocks may be formed by the extreme metamorphism of sediments *in situ*. There is the most complete proof that in the Schemnitz district the formation of true mineral veins, containing gold, silver, and other metals, has taken place within the most recent geological periods; in some cases, indeed, at a later date than the Pliocene.

Institution of Civil Engineers, April 25.—The first paper read was descriptive of the "Dhu Heartach Lighthouse," by Mr. David Alan Stevenson, B.Sc.—The second paper read was "On the changes in the tidal portion of the river Mersey, and in its Estuary," by Mr. James N. Shoolbred, B.A., Assoc. Inst., C.E.

May 2.—Mr. George Robert Stephenson, president, in the chair.—The paper read was on fascine work at the outfalls of the Fen Rivers, and reclamation of the foreshore, by Mr. W. H. Wheeler, M. Inst. C.E.

BERLIN

German Chemical Society, Feb. 28.—A. W. Hofmann, president, in the chair.—H. Ritthausen described a crystalline constituent of vicia sativa vicin, $C_8H_{16}N_3O_6$, which, treated with sulphuric acid, yields a sulphoconjugated acid, exhibiting blue reactions with baryta water and ammonia.—R. Schiff has transformed chloraechyl-aldehyde by heating it with acetate of potassium into the diacetate of ethylidene. The former body is therefore chlori-acetate of ethylidene,

$$CH_3\text{--}CH.Cl\text{--}O\text{--}CO\text{--}CH_3.$$

—R. Barth, by treating resorcine with hydrochloric acid, has produced an anhydride of resorcine, $C_6H_4OH.O.C_6H_4OH$, a dichroic substance, green in reflected light and red in solution.—O. Wilf published considerations on the constitution of organic dyes.—M. Nencky has found indigo in the urine of dogs fed with indol.—A. Oppenheim reported on various researches on aceto-acetic ether. Together with H. Precht, he has simplified the method for obtaining this substance in large quantities. The vapour density has been taken, and it has been explained why no hydrogen is evolved during the action of sodium on acetic ether; the reason being the transformation of acetyl, CH_3CO, into oxethyl, CH_3CH_2O. The same chemists have discovered a practical method for obtaining dehydracetic acid, $C_8H_8O_4$, by passing aceto-acetic ether through heated iron tubes. They described its ethyl-compound and the action of potash on dehydracetic acid: $C_8H_8O_4 + 3H_2O = 2C_2H_4O_2$ (acetic acid) + C_3H_6O (acetone) + CO_2. Baryta forms at the same time a substance resembling orcine. The same chemists found acetic ether, when heated, to yield ethylene and acetic acid.—A. Oppenheim and C. Emmerling have studied the action of oxydising agents on oxyuritic acid. The result is an acid, $C_7H_8O_3$, to which they give the name of hydro-oxybenzoic acid. By fusion with potash, it yields benzoic acid and water.

March 13.—A. W. Hofmann, president, in the chair.—Dr. Radziszewsky has transformed phenylacetic acid

$$C_6H_5 . CH_2 . COOH$$

into the corresponding aldehyde and alcohol; phenyl-ethyl-alcohol $C_6H_5 . CH_2 . CH_2OH$, liquids boiling at 207° and 212°. —F. Salomon has compared the properties of oxalurate of ethyl obtained by synthesis from urea with chloro-oxalate of ethyl with that obtained from oxalurate of silver. He has found them identical in the properties. Amongst other reactions he remarks that both with oxide of silver yield parabanate of silver. —V. Meyer and several of his pupils revert to the reaction which mixed azocompounds:—

$$C_6H_5N_2NO_3 + C_2H_4NO_2Na = NaNO_3 + C_6H_5N_2C_2H_4NO_2$$
Nitrate of diazobenzol — Sodium-nitro-ethane. — Nitro-ethyl-azophenyl

By generalising this reaction the following compounds have been prepared:—By V. Meyer: azonitropropylphenyl,
$$C_6H_5N_2C_3H_6NO_2;$$
by T. Barbieri: azonitroethylparabolyl, $C_7H_7N_2C_2H_4NO_2$; and azonitrophenylorthobolyl, $C_7H_7N_2C_2H_4NO_2$; by H. Wald: azonitroethylparabromophenyl, $C_6H_4BrN_2C_2H_4NO_2$; by F. Hallmann: azonitroethylnitrophenyl, $C_6H_4NO_2N_2C_2H_4NO_2$.—V. Meyer and M. Lecco described the following reaction:—
$$CH_3CH_2CBr_2(NO_2) + H_2NOH = 2HBr +$$
Dibromonitropropan. Hydroxylamine.
$$CH_3 . CH_2 . C = NOH(NO_2).$$
Propylnitrolic acid.

—W. Michler described the following reactions:—
$$COCl_2 + NH(C_6H_5)_2 = HCl + CO^{Cl}_{N(C_6H_5)_2}.$$
Oxychloride of carbon. — Diphenylamine — New chloride.

This, with ammonia, yields the urea, $CO(NH_2) . N(C_6H_5)_2$; and with aniline the urea, $CO(NHC_6H_5) . N(C_6H_5)_2$. Oxychloride of carbon and ethylaniline yields the chloride—
$$CO^{Cl}_{N(C_6H_5)(C_2H_5)}.$$
If, instead of monoethyl-aniline, dimethylaniline is submitted to the action of oxychloride of carbon, the reaction passes in a different manner, namely:—
$$2N(C_6H_5)(CH_3)_2 + COCl_2 = HCl\ N(C_6H_5)(CH_3)_2 +$$
Dimethylaniline — Hydrochlorate of dimethylaniline
$$N(CH_3)_2C_6H_4COCl$$
Chloride of dimethylamidobenzoic acid

The acid is easily obtained, and proves to be identical with dimethylamidoparabenzoic acid.—P. Claessen proved the identity of rhodan-acetic acid of Heintz with what Vollhardt called isosulfocyano-acetic acid.—C. Reimer has obtained the following very remarkable result of the action of chloroform on an alkaline solution of phenol, viz., salicylous acid. This reaction may be generalised. Cresol and other phenols offer similar results.—O. Braun described an apparatus destined to retain the solid and liquid parts of smoke, as also those parts that may be absorbed by solids or liquids. He likewise described a similar apparatus for retaining sparks.—E. Schunk and H. Roemer gave details on the preparation of isoanthraflavinic acid and a comparison of its properties with anthraflavinic acid. The described substitution-derivatives with four atoms of bromine and with two molecules of acetyl, ethyl, and methyl respectively.—F. Tieman has transformed vanilline by acetic anhydride into a coumarine. The corresponding acid is ferulic acid. He drew attention to the relation of vanillinic and coniferylic derivatives which corresponds to that of benzoic and cinnamic compounds.—F. Tiemann and H. Haarmann have found in vanilla besides vanilline, vanillic acid, resin, and fat.

PARIS

Academy of Sciences, May 1.—Vice-Admiral Paris in the chair.—The following papers were read:—Discovery of the small planet (163), M. Leverrier. It was discovered at Toulouse, April 26, by M. Perrotin.—On the electro-motive forces produced on contact, of liquids separated by capillary diaphragms of any nature, by M. Becquerel. Using dilute instead of concentrated liquids, he finds the electromotive force increases with the time of contact reaching a maximum. The action probably consists of a condensation of acid and alkaline particles on the faces of the diaphragm, just as gases are condensed in porous bodies.—On the oscillations of temperature of half January, half February, and half April, 1876, by M. Sainte-Claire-Deville. In April there was a minimum about the 15th; in January and February about the 12th.—On microclinic felspar and on andesine, by M. Sainte-Claire-Deville.—Microscopic examination of orthose and of various triclinic felspars, by M. Des Cloizeaux.—On electric polarisation, by M. Du Moncel. An electrified plate sheathed with oxygen may produce a different effect from an unelectrified plate so sheathed, the electric vibrations continuing after the electric source has ceased (phosphorescence is analogous). The author studies this with hard stones, he also studies the effects of polarisation with induced currents, effects of local currents in stones, &c.—Note on the theory of several hydraulic machines of his invention, by M. De Caligny.—On the embryogeny of Ephemera, especially that of *Palingenia virgo* (Olivier), by M. Joly.—On fishes of the Ceratodus group in the river Fitzroy, Australia, by M. de Castelnau.—New researches on gallium, by M. Lecoq de Boisbaudran.—Experiments on solar heat, by M. Salicis. A sealed packet (of 1868) relating to utilisation of solar heat by reflectors, &c. He describes a heliodynamic and a heliostatic apparatus.—Researches on the compounds of pure carbon in meteorites, by Mr. J. Lawrence Smith.—On the Phylloxera which comes from the winter egg, by M. Boiteau. Direct application of sulphide of carbon in the treatment of phylloxerised vines, by M. Allies.—On a new mode of cultivation of the vine without pruning, by M. Martin.—On the employment of the method of articulation in education of deaf mutes, by M. Houdin.—Observations of planets at the Observatory of Marseilles, by M. Stephan.—Phenomena of interference obtained with thin sheets of collodion, by M. Gripon.—On the distribution of magnetism in cylindrical bars, by M. Bouty.—On the transmission of electric currents by derivation across a river, by M. Bouchotte; an experiment made in 1858. An air line of 300 m. (with battery) on one bank of a river, was connected by both ends to earth, and a similar line on the other bank contained a galvanometer. On the battery circuit being closed, the needle was deflected.—On a new system of electro-magnet with flat spirals, by M. Serrin. The wires of bobbins of electro-magnets, used in regulators of powerful electric lights, sometimes become so hot as to fuse the insulating matter surrounding them. M. Serrin forms his electro-magnet spirals of metallic helices without insulating cover, and so arranged that the spirals cannot touch one another. He hollows out his helice from a copper cylinder of thickness equal to that of the bottom, and he covers the coil with vitreous enamel. The spiral may be raised to a red heat without the sensibility of the apparatus being affected. On a new sulphate of potassium, by M. Ogier.—On the origin of stripe in puddled iron, by M. Le Chatelier. The stripe results from small fusibility of partially peroxidised scoriæ, and from the comparatively low temperature at which the puddling is done.—On a new crystallised organic substance, by M. Loiseau. It is called *raffinose*, and was got in investigating the most favourable conditions for extraction of sugar from molasses by means of the sucrate of hydrocarbonate of lime. Crystallised raffinose has the formula $C_6H_7O_7$.—On a new method of studying the respiration of aquatic animals, by MM. Jolyet and Regnard. The object is to keep the medium always in the normal state, however long the experiment. In a limited closed space, containing determinate quantities of water and air, it was required to make air circulate in the water, to absorb the CO_2 in proportion as it was exhaled, and replace O as it was consumed. A figure of the apparatus is given.—On the crystalline system of various substances presenting optical anomalies, by M. Mallard.—The elephants of Mont Dol; dentition of the mammoth; distinction of upper and lower molars, right and left, by M. Sirodot.—On the cranial cavity and the position of the optic orifice in *Steneosaurus Heberti*, by M. Morel de Glasville.—On a new thermo-cautery, by M. Paquelin. It depends on the property which platinum has, of becoming incandescent (once it has been raised to a certain degree of heat) in a gaseous mixture of air and of certain hydrocarbonised vapours.

CONTENTS

P

others, the qualities in which they themselves are deficient. Aided in the work of comparison by the purely scientific system of classification now first adopted, the investigator will find much to suggest new trains of thought, as the science teacher will find new and improved means for inculcating the truths of nature. While the scientific instructor, the student, and the mechanician will find enough to absorb their interest, the general public will find infinite interest in much of the apparatus exhibited.

"There are already indications that the magnificent collection of scientific treasures brought together at the cost of much ability and energy on the part of the authorities of the South Kensington Museum will hardly be permitted to suffer redistribution to the four corners of the earth. Certain precious relics—the pride of Universities and museums—will probably be claimed at the conclusion of the Exhibition by their proper owners; but it is more than doubtful whether the makers of many of the most perfect modern instruments would not prefer them on view for an indefinite period rather than withdraw them altogether. Many of them have signified their willingness to present the nation with their exhibits out of hand, and there are other signs that a project not new, but dormant for some time past, will shortly be revived. It is that of establishing in London an analogue of the Conservatoire des Arts et Métiers at Paris, of which a very poor imitation, if it can be called an imitation at all, exists in the Patent Museum. The present opportunity of forming a scientific and industrial museum, which would be the envy of Europe, appears to many scientific people too good to be lightly foregone."

The *Standard*, in an article on Wednesday last week, says:

"The result is a collection which will delight the heart of every scientific man, and even to those who merely dabble in science the interest will be very great. . . .

"That the new loan collection of scientific instruments will be an exhibition popular with and largely frequented by the general public was probably never expected by its originators, but to scientific men, whatever be the branch of the subjects to which they give their attention, the collection will be of the highest interest. In its way it is certainly altogether unequalled, and we may presume that the intelligent pleasure of the comparatively small number of visitors will amply compensate its originators for the absence of the classes who have formed the vast majority among the patrons of the former international exhibitions."

The *Daily Telegraph* of Monday writes as follows:—

"By her presence on Saturday at the assembly which has thus hopefully preceded the public opening of the exhibition in the galleries bordering the garden of the Horticultural Society, the Queen stamped with an approval not less enlightened than gracious and kindly the most interesting and valuable scientific display that has ever been organised in this or any country of the world. . . .

"Many discoveries have been and are yet to be achieved by means of instruments exhibited in that grand collection at South Kensington; and we may reasonably infer that had it not been for the invention of certain apparatus the most important natural truths must have remained unknown. In the Loan Exhibition at South Kensington is laid the basis of a Science Museum such as was strongly recommended in the report of the Royal Commission on Scientific Instruction, over which the Duke of Devonshire presided. The Conservatoire des Arts et Métiers in Paris appears to have been the model observed by those most interested in the new scheme; and, the co-operation of foreign countries having been obtained, a collection which illustrates the past struggles as well as the existing triumphs and aspirations of science is now accessible to all who desire instruction of so wide and so elevating a character.

"Though it is utterly impossible within the compass of this notice to indicate a hundredth part of the wonderful attractive collection spread through these five rooms upstairs, we may at least assure all intending visitors that, with catalogue and handbook to guide and assist them, they may employ, to inestimable profit, half a long day in looking at object after object, and will then feel the necessity of another visit. Such a book [the Handbook] is a cyclopædia of useful knowledge in itself. Nor can the admirable arrangement of objects be passed over without praise. The inevitable fatigue of studying attentively a vast scientific museum is reduced as much as possible by the perfection of system and method, in classifying the objects, and in placing them well within view."

The *Engineer* says:—

"Owing to the excellent organisation which was made at an early date, and the support which has been afforded from all quarters, the exhibition seems likely to be even a greater success than was ever dreamt of when it was at first proposed."

Speaking of the Conferences the same journal goes on to say.

"If these lectures and discussions are printed and collected into a volume, as there is some talk of doing, a most valuable addition to scientific literature will without doubt be made, especially if permanent photographs of the chief objects be taken and added to it by way of illustration. The conference room, however, is very small, and a bad shape for such a purpose; and if the meetings are as fully attended as one may expect them to be when lectures are to be delivered by such gentlemen as we have above mentioned in connection with the mechanical section, and by equally eminent ones in other sections, there is every likelihood that it will be found altogether too small and confined, in which case most probably the meeting will adjourn to the arena of the Albert Hall. There can be no doubt that the exhibition and meetings themselves will do much to further science in this country, but it is hoped that still more lasting results will accrue, as was shadowed forth by the Lord President and the Vice-president of the Council on Education, the Duke of Richmond, and Viscount Sandon, at the first meeting of the general committee, who referred to the recommendations of the Royal Commission on Scientific Instruction with regard to the creation of a science museum, and expressed a hope that the loan collection might become the means of developing the educational and other departments of the South Kensington Museum into a similar museum to the Conservatoire des Arts et Métiers in Paris, which would tend to the advancement of science and industrial progress in this country."

Last week's *Iron* speaks of the collection as follows:—

"The success of the Loan Collection of Scientific apparatus, to be inaugurated by the Queen this day (Saturday) is no longer a matter of doubt. The invitations to contribute have been responded to by the scientific world, both at home and abroad, with singular liberality, while the mass of material which has flowed in from all quarters has been dealt with by able and judicious hands. That the opening should have been somewhat delayed seems, too, rather a matter for congratulation than otherwise, as the completeness of the exhibition has been in consequence increased. Of the five sections under which the exhibits are grouped, it is true that some are still inadequately represented; but the very great interest of the physical and mechanical groups more than compensates for any deficiencies under the heads of chemistry, biology, and geology.

"The particular advantage which attaches to this latest modification of the now somewhat discountenanced International Exhibition is, that it brings together apparatus and models which the most attractive World Fair would never have drawn from their retirement. Men of science and students, as a class, are not influenced by the inducements which are most operative with ordinary exhibitors; but none the less is it necessary for the advancement of knowledge that their treasures should be, from time to time, examined and criticised by their fellows.

"There is much of interest in the geological and geographical sections, though nothing very new. Of the metallurgical division—with a miserable dozen exhibits out of a total of nigh on five thousand—what can be said? Is metallurgy devoid of scientific interest? Or has one of the greatest of England's industries no followers who care to do anything for its advancement? With this sole exception, the Science and Art Department must be held to have scored a great success, and to have saved the Government from the reproach of doing nothing for science. It only remains to hope that the magnificent collection which now fills the exhibition galleries will not be dispersed without an effort being made to secure for the nation such portion of it as may be obtainable, and suitable to form the nucleus of a technical and scientific museum, on the plan of the Conservatoire des Arts et Métiers of Paris and the similar institutions to be found in every large German city."

Such is what may be called "lay" opinion upon the importance and success of this unprecedented Collection; and that this opinion is endorsed by that of men of science themselves may be seen from the addresses of Mr. Spottiswoode and Dr. Siemens, which we are able to publish to-day.

THE REMINGTON TYPE-WRITING MACHINE

In making comparison between the physical and the biological sciences, it is not difficult to recognise how it comes that they differ in one essential element. In the *physical* the forces in action are comparatively few, and of very different degrees of intensity. The centripetal and centrifugal tendencies, for instance, of moons and planets so far exceed the mutual attractions of the planets *inter sese*, that in the rough calculations of their orbits the latter may be omitted from consideration.

In the study of the phenomena of life, however, the innumerable forces which are found to be in play are so fairly balanced in their magnitude and tendencies, that the task of dissociating and classifying them is almost beyond the means at the disposal of the human mind.

In the study of the various machines which have from time to time been constructed with the purpose of economising or superseding the employment of the engine—muscle, expensive in the nature of the fuel it requires, although it is so economical in the way in which it uses it, a similar division may be made. In the steam-engine, however developed, the waste of force essential to the working of the valves is nothing in comparison to the power employed, nor in the telegraphic needle is much done by the current except the actual record which it makes.

But on looking at the sewing-machine or the more novel type-printing apparatus we can see that the ingenuity of America, stimulated by the idea of practical advantage, has been developed in a direction, not towards the discovery of more economic principles, but to the employment of forces already known in the mastery of complicated operations previously thought to be beyond the powers of any other mechanism than the hand of man. To obtain these results an entirely different conception has to be introduced. The power at the disposal of the operator has not to be directed simply to the performance of a single operation, like the movement of the needle in the sewing-machine or the impressing of the letter in the type-writer, but has to be distributed so that it may perform a series of simultaneous operations, all leading to a complicated result. The treadle of the sewing-machine in its movement, besides the rise and fall of the needle which it produces, works the thread loop-slip, shifts the fabric, and unwinds the cotton. The pressure on any one of the keys of the type-writer, besides the impression which it stamps upon the paper, shifts that paper, inks the type, and places each letter in its proper sequence.

In order properly to balance all these varied actions, great ingenuity and much practical experiment are necessary, and of the "Remington Type Writer," the only satisfactory instrument of the kind yet brought to public notice, the introducers, the most prominent of whom is Mr. Jefferson M. Clough, superintendent of the Remington Armoury, tells us that "during the time required to perfect the invention, about fifty machines were constructed, all upon the same general principle, but each differing more or less in the minor details."

This general principle is a most ingenious one. It is evident that the great difficulty in the construction of such an instrument is that it is necessary to have a large number of signs—letters of the alphabet, figures, stops, &c., arranged in such a manner that any one of them may, by the simple pressure on a corresponding key-note, be printed in any required order or sequence upon a paper sheet placed ready to receive it. There are many more or less elaborate ways in which this may be accomplished; none, we believe, so simple as that adopted by the Messrs. Remington. Their apparatus may be compared to a piano, even in its details. There is a key-board, on each key of which the letter it impresses is to be found indicated. The depression of each key raises a hammer. This hammer, however, instead of being covered with a felted pad, as in the piano, carries at its extremity a type-cast letter, which, in place of a stretched wire, strikes on a piece of paper the impression of the letter which it bears. So far the similarity between the two instruments is very close. But to produce sounds and to perpetuate impressions in black and white in any definite sequence, are two very different things, the latter being much the more difficult; and herein lies the ingenuity of the principle adopted in the type-writer. The hammers, instead of being arranged in one line, as in the piano, form a circle, in the exact centre of which each type-letter at the end of its hammer-lever strikes upwards. Two keys struck at the same time must consequently cause two type-letters to clash in their attempt to reach the same spot, the centre of the circle. This, however, does no injury to the instrument, although care must be taken not to cause it. Above the circle of levers the recording paper is situated, rolling on a drum, towards the operator, the whole being so placed that just before any letter of a word is struck that part of the

paper on which the letter has to be impressed is nearly over the middle of the lever-circle. The depression of the key first moves the paper into the exact position and then prints the letter, figure, or stop. An independent key produces the blank between each two words.

The method of inking is excellent and unexpected. A strip of fine fabric, saturated with the ink is carried between two rollers so arranged that it intervenes *between* the paper to be printed on and the centre of the lever-circle. The type-carrying hammers do not, therefore, strike the paper itself at all, but only the ink-saturated band, which, as a result of the percussion, comes in contact with the recording paper, *but only in the parts where contact is made*, which are nothing more nor less than those corresponding to the configuration of the letter or figure employed. There is a simple shifting apparatus to carry this inking band from one roller to the other, and afterwards back again, which prevents the same part from being struck too often.

A side lever shifts the paper at the end of each line, and a small bell is struck to warn the operator when this has to be employed.

Into further detail we need scarcely enter. The whole instrument is not larger than a sewing-machine. Its cost is twenty guineas. It only writes in capitals, the total number of keys being forty-four, arranged in four rows of eleven in each. Its simplicity is the best guarantee of its durability.

As to the "typoscript" (in contradistinction to the manuscript of ordinary handwriting), there is no comparison between its clearness and that of average penmanship. It has, in fact, all the appearances of print, with its many advantages as regards legibility, compactness, and neatness. Errors, if detected soon enough, can be corrected by the repetition of the word or sentence, and the subsequent obliteration, upon reperusal, of the faulty lines. The ink employed can be transferred like transfer ink.

The principal question which this beautiful and ingenious little instrument suggests to our minds is, whether it would not be better for every one of us to learn the Morse telegraph language, and employ it for writing upon all occasions instead of the cumbrous letters now in vogue. Thought is more quick than formerly. Germany is rapidly rejecting its archaic type; why should we not go further and write in Morse, where spots and horizontal lines do duty for all necessary signs, and type-writers of the simplest form would be required?

ORIGIN OF LIFE

On Fermentation. By P. Schutzenberger, Director at the Chemical Laboratory at the Sorbonne. With twenty-eight Illustrations. (Henry S. King and Co., 1876.)

Sur la Génération des Ferments. Par E. Fremy, Membre de l'Academie des Sciences, Professeur de Chimie à l'Ecole Polytechnique et au Muséum d'Histoire Naturelle. (G. Masson, Editeur, Libraire de l'Académie de Médecine: 1875.)

Evolution and the Origin of Life. By H. Charlton Bastian, M.A., M.D., F.R.S., Professor of Pathological Anatomy in University College, London. (London Macmillan and Co., 1874.)

THE work on fermentation is one of the International Scientific Series. Starting with a thoroughly philosophical conception of his subject, the author points out that from our present stand-point of knowledge, all those phenomena classed together under the name fermentation, are but special cases of the chemical phenomena of life. To life, however, we are not to attribute any extra-material force or influence. Though the force that can reduce the complex chemical edifice called sugar in a certain determinate direction, is manifested only in the living cell of the ferment, yet this "is a force as material as all those we are accustomed to utilize." "In other words, there is really no chemical vital force. If living cells produce reactions which seem peculiar to themselves, it is because they realise conditions of molecular mechanism which we have not hitherto succeeded in tracing, but which we shall, *without doubt*, be able to discover at some future time." In the book will be found a clear and concise statement of our present knowledge of fermentation, and a brief history of the progress of opinion and research. The outstanding questions (and there are many) and diverse opinions are presented with scientific impartiality, as is also contradictory evidence. It is gratifying to observe how such rival theories as those of Liebig and Pasteur on the nature of fermentation can be swallowed up in a larger conception, and one at least of the combatants conclude that both may be right. "Fermentation," says Liebig, "is a movement communicated by instable bodies in process of chemical transformation." "I maintain," says M. Pasteur, "that the chemical act of fermentation is essentially a phenomenon correlative to a vital act." "So be it," replies Liebig, "'a vital act' is a phenomenon of motion; your special views fall within my theory." Necessarily large space in this work is given to the extensive and splendid researches of M. Pasteur, whose views the author follows in the main, though not at all times able to find them quite self-consistent or consistent with admitted facts. On the great question of most general interest—What is the origin of ferments? he adopts the conclusions of M. Pasteur.

The origin or generation of ferments is the subject of the work by M. Fremy, who has long and ably contested the theory maintained by M. Pasteur. According to this last distinguished chemist, all ferments are the offspring of living things similar to themselves; and when these organisms appear in any liquid, such as milk, or the juice of the grape, it is because the germs or eggs of these creatures have in some way been introduced into the liquid. M. Pasteur has made a great many interesting and most important experiments which to his mind demonstrate the doctrine of panspermism. The demonstration, however, is not universally accepted; and M. Fremy is among those who find it possible to admit the accuracy of most, if not of all, M. Pasteur's experiments without accepting his conclusions, while they in their turn bring forward observations and experiments which they hold to be quite irreconcilable with the hypothesis that ferments are always produced from germs of similar organisms. We can in no way refer to the innumerable experiments; we may, however, try to give in a few words some faint conception of the character of the discussion.

Whence, for instance, come the well-known organisms which appear in the expressed juice of the grape, and are invariably associated with alcoholic fermentation? "From germs that have found access to the liquid," says M. Pasteur. "No," replies M. Fremy, "they are evolved,

as are all ferments, from the substance of the organic medium in which they appear." Now panspermitists have always taken for granted that the air is a vast reservoir of germs, all sorts of which they farther assume are everywhere and at all times being deposited on all solid and liquid substances. In perfect accordance with this opinion it was found that when the must of grapes was boiled to kill any germs that might have already got into it, and kept in a small flask from which the solid particles floating in the air were excluded, no fermentation took place. But, say the supporters of heterogenesis, that may not be because germs could not get in, but because by boiling you killed the vegetative life of the liquid. Well, answers M. Pasteur in triumph, it is all the same if you don't boil it. "Du suc de raisin pris dans l'intérieur du fruit et du sang retiré directement de la circulation se conservent sans altération, si on les préserve de l'influence des poussières atmosphériques. Dans ce cas, on ne peut pas invoquer la mort, par l'ebullition, des substances hémiorganisées vivantes qui existent dans le liquide." This is the fact which to M. Pasteur's mind ought to put an end to the discussion. The readers of NATURE know how he has used it against Dr. Bastian in his letter to Prof. Tyndall (NATURE, vol. xiii. p. 305), and the uninitiated might well look on this as a decisive blow; but the end is not yet. It was suggested long ago that in all experiments of this class the air in contact with the liquids described by Pasteur as "l'air pur, privé de ses poussières flottantes," soon became changed from its normal composition; it loses its oxygen, the presence of which is held to be an essential condition of the development of the alcoholic ferment. But this is not all. If the air contains the germs of the alcoholic ferment, "Why is it," asked M. Fremy very naturally, "that liquids in which this organism propagates and multiplies very rapidly if once introduced do not enter on fermentation when left exposed to the air?" Here is M. Pasteur's remarkable answer: "C'est que cette liqueur s'est couverte de moisissures; la place étant prise par les mycodermes, les ferments n'ont pas pu se développer." One step more. M. Pasteur has elaborately collected the dust from the atmosphere and carefully sown it in various prepared mediums without, however, once succeeding in obtaining alcoholic fermentation, although he sowed this dust in a liquid most suitable for the development of the alcoholic ferment. How has this awkward-looking fact been met by the advocates of the germ theory? Very simply, thus: Well it would appear, they observe, that after all the germs of the alcoholic ferment are not in the atmosphere, but the ferment always comes from germs nevertheless; the germs are on the surface of the grapes themselves. And M. Pasteur is ready with an experiment to prove it. Of course M. Fremy is equally ready with experiments and arguments to prove that it is not so.

Our space will not permit us to pursue the subject further. The morsel of the discussion which we have been able very imperfectly to present may, we hope, enable the general reader to perceive that we are still some way from that settled peace which follows victory. We make no pretence to have stated M. Fremy's case; the subject is intensely interesting, and we heartily recommend his book as a model of scientific discussion. In point of scientific temper he has altogether the advantage of his brilliant antagonist.

The following notice of Dr. Bastian's "Evolution and the Origin of Life" was written and put in proof a long time ago. It would have never been published, but for the fresh interest that Prof. Tyndall has given to the question.

It fell to the writer of this notice to review Dr. Bastian's "Beginnings of Life" (*Examiner*, Aug. 31, Sept. 14 and 28) on its publication in 1872. Our first words were these:—"One after another our ablest scientific workers are bringing the fruits of their labours and dedicating them as it were, humbly, to that profound philosophy of evolution of which Mr. Herbert Spencer may be said to be the prophet. In the work before us Dr. Bastian has attacked the enemies of evolution in what they have hitherto considered the very citadel of their strength. His chief point is that living organisms are evolved out of dead matter, containing neither spore nor germ, nor any such thing." Such was, and remains, our opinion concerning the relation of Dr. Bastian's researches to the theory of evolution.

It is part of the doctrine of evolution that living matter was once at least evolved from dead matter—from dead inorganic matter. Is there, then, or rather ought there to be, any inherent improbability in the supposition that living

Unless the conditions of life-evolution are known, and are known not to exist in the present state of our globe, the probability is surely the other way. Now the essential conditions of the process are, and will certainly remain for a very long time, one of Nature's darkest secrets. Why then do certain evolutionists so obstinately resist the assertion that Archebiosis has actually been known to take place. We cannot enlighten our readers on this point; nobody has ever been able to say why Dr. Bastian must be wrong.

At the same time, in trying to force evolutionists either to accept his conclusions or to stand convicted of inconsistency, Dr. Bastian may perhaps be held guilty of a little straining. Though we believe with Dr. Bastian that life-evolution is an every-day process, still we cannot agree with him that "the existence of such lowest and simplest organisms as the microscope everywhere reveals at the present day, is quite irreconcilable with the position that life-evolution has not occurred since an epoch inconceivably remote in time." To put somewhat strongly the reply of those who do not follow Dr. Bastian to this conclusion, his contention here is not unlike the reasoning of those critics of Mr. Darwin who argue that *if* men have been developed from monkeys there ought now to be no monkeys, for the plain reason that they ought to have all developed into men. The existence of lowest organisms may perhaps be irreconcilable with the position that life-evolution has not occurred since an epoch inconceivably remote in time, when coupled with Dr. Bastian's belief that *in living matter* there is "an internal principle or tendency leading to progressive complexity of development," whereby every living thing is kept constantly on the stretch for an opportunity to spring forward to a more complex structure. But this conception of an inherent principle of organisation, which, we must confess, appears to us rather ill-defined and unscientific, is

not a part of the theory of evolution, and is expressly repudiated by Mr. Spencer and Mr. Darwin. Now, to those who know nothing about a "principle of organisation," there is no difficulty in conceiving lowest organisms remaining lowest organisms through a time indefinitely long. Indeed, what Dr. Bastian teaches concerning his world of Ephemeromorphs makes the conception very easy. "The complexly-interrelated individuals constituting this vast underlying plexus of infusorial and cryptogamic life must," he says, "remain wholly uninfluenced, so far as their form and structure are concerned, by what Mr. Darwin has termed 'Natural Selection.'" Surely it is quite as easy to conceive the mass of these ephemeromorphs going on for ever in an endless round as it is to picture one of them here and there setting out on its course of ascending development. But though Dr. Bastian, after proving his case, may have been somewhat zealous to convince the world and to confound his adversaries, no dispassionate reader of his books can fail to be struck with the simplicity and clearness of the reasoning, and the truly scientific candour of the author.

The complete argument is contained in this book, which may be profitably read by those who have not time to go through the larger work. Since the publication of that work some progress has been made. "Well-informed men of science," says Dr. Bastian, "no longer doubt that swarms of bacteria can be made to appear within sealed glass vessels containing suitable fluids, after the vessels and their contents have been exposed to the temperature of boiling water." That is, Dr. Bastian's experiments, which were at first discredited, have been verified by other workers, some of them with no bias towards a belief in spontaneous generation. But with this fact all well-informed men of science have not accepted Dr. Bastian's conclusion that these living things are evolved from dead matter. Not believing in spontaneous generation, they first supposed that Dr. Bastian must have bungled and deceived himself, because they had every reason to believe that living matter could not resist the temperature of boiling water. They are now obliged to admit that Dr. Bastian was not mistaken. Some, however, admitting this, prefer to give up their well-supported belief in the killing power of boiling water, rather than break with the sacred dogma, *omne vivum ex vivo*, in support of which they can now urge no single fact or argument.

In the treatise before us Dr. Bastian collects a great deal of evidence as to the amount of heat requisite to destroy life, which, summed up, amounts to this: "that all known forms of living matter with which accurate experiment has been made invariably perish at or below 140° F." And he details experiments of his own, in which living organisms appeared "within closed flasks which had been previously heated to 270-275° F. for twenty minutes, and to temperatures of over 230° F. for one hour." Having done this much, Dr. Bastian might, we think, rest satisfied for the present. If his readers fail to appreciate his facts, the little lessons in logic to which he occasionally treats them will not, we fear, help them much. We would also observe that though error may die hard, yet, if he has given it its death-wound, there is no great purpose to be served by triumphing over its last struggles and agonies. "Victorious along the whole line" may now be said of spontaneous generation with much greater truth than it was asserted by Prof. Huxley of the contrary view in 1870. With the facts as they now stand, it appears to us that no adverse criticism can do anything to shake the position which Dr. Bastian has given to the doctrine of the *de novo* origin of life. Some of the attempts that have been made to escape Dr. Bastian's conclusion, after admitting his facts, are curiosities in the way of scientific discussion. Now it is suggested that germs may have been protected from the destroying heat in the inside of enormous lumps almost as large as a pin's head. Again, and still better, that the germs of bacteria may escape death by reason of their excessive smallness. This last is a very happy thought, and deserves to be thoroughly worked out.

In conclusion, we would impress on those of our readers who may take some interest in this question, that there are special reasons why they ought not to rest satisfied with any second-hand statement. If they would know Dr. Bastian's case, they must read his book, which, thinks an American philosopher, Mr. Fiske, "may perhaps mark an epoch in biology hardly less important than that which was inaugurated by Mr. Darwin's 'Origin of Species.'"

Such was the light in which the question presented itself to one who, before studying Dr. Bastian's works, had passively accepted the doctrine *omne vivum ex vivo*. Only when we read Prof. Tyndall's paper of Jan. 13 did we find how far we were mistaken in supposing that the high honour of having settled a great question and added an important truth to our stock of science was about to be awarded to Dr. Bastian by universal consent. Certainly if we are to take Prof. Tyndall—a science teacher for whom we have the highest respect and admiration as our guide and instructor on this subject, we might well blush at the youthful precipitation with which we threw ourselves into the arms of Dr. Bastian. We can only say that we had conscientiously tried to follow the controversy, and to make ourselves acquainted with the alleged and accepted facts. We honestly believed, and still believe, that we were making a simple statement of fact when we said, that Dr. Bastian's experiments, which were at first discredited, have been verified by other workers, some of them with no bias towards a belief in spontaneous generation, and that this was known to "well-informed men of science." When Prof. Tyndall says that he was "certainly not among the number" to whom the truth of Dr. Bastian's assertions was known, the phrase is slightly ambiguous. Of course Prof. Tyndall does not mean that he did not know that Dr. Burdon-Sanderson, for example, had by careful experiment established to his own satisfaction, though contrary to his expectation, that Dr. Bastian was accurate in his statement of fact. That Prof. Tyndall supposed it probable that Dr. Bastian and Dr. Burdon-Sanderson had committed "errors either of preparation or observation," and that he himself, were he to try, might escape such errors, is evidenced by his undertaking the course of experiments which for the present makes the question once more one of evidence. It was in this sense that Prof. Tyndall "did not know;" but in this sense it would have been an impertinence on our part, and even on the part of most "well-informed men of science" "not to know."

One word remains to be said. The question at issue is

of profound biological importance with large practical bearings. It would be a disgrace to science, or rather to scientific men, were the present uncomfortable dead-lock of conflicting evidence to be permitted to remain for any length of time. Prof. Tyndall will, of course, publish descriptions of his experiments in the fullest possible detail; but the interested public have no just balance in which to weigh the accuracy and skill of Prof. Tyndall against that of Dr. Bastian. The high position of our great teachers undoubtedly carries with it certain obligations; and we scarcely think that we ask too much in the interest of science when we venture to suggest that steps should be taken towards the little friendly arrangement necessary for the settlement of the question.

DOUGLAS A. SPALDING

OUR BOOK SHELF

Solid Geometry. By Percival Frost, M.A. Vol. i. pp. 422. (London: Macmillan and Co., 1875.)

THIS excellent treatise is a revised and considerably enlarged second edition of the similar treatise brought out some few years since under the joint editorship of Messrs. Frost and Wolstenholme. The engrossing duties consequent upon Mr. Wolstenholme's holding the post of Professor of Mathematics at Cooper's Hill, have prevented his taking part in the bringing out of the present work. Great additions have been, and are being, made in this subject, as may be inferred from the fact that this first volume consists of 422 octavo pages, and even in this space many modes of treatment are omitted. "We cannot, however," writes Mr. Frost, "in a volume of moderate compass, pretend to include all the dual results to which our equations might give rise, but must confine ourselves to a development of the methods most generally useful."

The author reserves for his second volume "those parts which are chiefly interesting as pure geometry," bringing into the volume before us as much as he could, those parts of the subject which are more especially required by students who take up physical subjects. Prefixed to the text is a full table of contents: indeed both in this work and that by Dr. Salmon on the same subject, the full list reminds us (though drawn up on different principles) of the diagnoses of the natural orders prefixed to text books on the British flora.

The text is written with extreme lucidity, and the difficulties to be met with in its perusal do not arise from the style, but from the inherent difficulty of the matters treated of. In two or three places we come across the phrases "easy to see," p. 154, "not hard to show," p. 157, and the like; of course here they are not intended to cover inability to expound the matter within reasonable compass, but still we think the proof might have been sketched out. When the student is going through the text step by step, he may even be able to work out the process by himself, but it is not so easy when the book is taken up at other times, when the previous steps in the reasoning are not fresh in the mind.

We note in Art. 192 that the elliptic sections are not pointed out; this and the definition of the *radical plane* (§ 166) which reads somewhat curiously to our mind, are the only defects we have been able to detect—we had marked many passages for comment, but all is so carefully done, and the work brought down to the latest discoveries, [illegible] content ourselves with saying that the book is well entitled to a place by the side of Dr. Salmon's treatise. Mr. Frost, it is well known, employs the term "conicoid" for the surface of the second degree, and in the present work he gives his reasons for persisting (as he expresses himself) in retaining the term. We must just cite here the concluding part of his remarks; the surface of the second degree, "well deserves a distinctive name instead of being recognised only by its number, a mode of designation which, I am informed, a convict feels very acutely. Man might be always called a biped, because besides himself there exist a quadruped, an octopus, and a centipede, but, on account of his superiority, it is more complimentary to call him by some special name."

The list of typographical errors is, we believe, very small, and all are easily corrigible by the reader. The appearance of the book leaves nothing to be desired.

Physiologische Methodik: ein Handbuch der Practischen Physiologie. Von Dr. Richard Gscheidlen, Professor an der Universitat zu Breslau. Erste lieferung.

DR. GSCHEIDLEN has undertaken to supply physiological students with a book which undoubtedly they very much need. He proposes to give a detailed and full account of the instruments and methods of practical physiology, and to consider the experimental basis on which our knowledge of the functions of the animal body are founded.

The book is to be published in parts; the first part, which we have before us, treats at considerable length of the measurements of volume, temperature, time, &c. needed in physiology and of the various instruments used in such measurements. It contains also the beginning of a chapter on physiological instruments and methods in general.

Altogether the present part gives good reason to hope that the work, when completed, will not only succeed in its main object of being useful to beginners, but will also be a valuable book of reference in physiological ways and means. We shall, however, reserve detailed criticisms till the book is published as a whole.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.]

Periodicity of the Fresh-water Lakes of Australia

THE fresh water lakes of Australia, though insignificant in size in comparison with the extent of the country, possess several features of considerable interest to the naturalist. Lake George, which is generally considered the largest sheet of fresh water on the Continent, is only some twenty-three or twenty-four miles in length and seven miles in breadth at the widest part, and even this lake had no existence twenty-four years ago. A bit of swampy ground across which drays could pass, occupied, in 1852, what is now the lowest part of the lake-bottom, and the rest was taken up by squatters and small farmers, who little dreamed, when they settled on the rich alluvial plain, that within a few years they would be hopelessly driven from their homes by the advancing waters. The present lake is situated, at an elevation of about 2,000 feet above the sea, at the lower end of a shallow basin formed by a fork near the southern extremity of the Blue Mountains, and about 150 miles from Sydney. This basin is some forty to fifty miles in length, and from fifteen to twenty miles in breadth, the mountains rising somewhat rapidly to a height of several hundreds of feet on every side except the south. The depth of the water at the present time is only from 25 to 30 feet, which, considering the extent of land submerged, affords a strong argument in favour of the supposition that the lake existed in past times, and was at least as extensive as it is now. An examination of the banks of the creek which runs into the head of the lake confirmed this hypothesis, and led me to believe that it has at one time been much more extensive than it is at present, for the horizontal layers of alluvial deposit could be traced along either bank at an elevation of 10 or 12 feet above the present lake-surface. This, however, could not have been the case within the last one hundred years—probably not within many hundreds of years—for the present lake is fringed with broad expanses of partially submerged forest trees, that must have attained a growth of more than a century before the waters

overtook them. It may, therefore, I think, be assumed that the lake has never in recent times been so extensive as it is now, but that formerly it was much more so.

It will naturally be asked, What are the causes of its recent rapid growth, and what is likely to be the end of it? Without doubt the chief cause lies in the killing of the trees, which, until lately, covered almost uninterruptedly the whole basin except the lowest portion. The water is thus drained rapidly into the lake, and the surface exposed to evaporation reduced to a minimum. The trees have been destroyed chiefly by the squatter, in order to let in the sun and improve the grass. But another and unexplained cause has been at work during recent years destroying the bush, and the trees have died away mysteriously at the rate of scores, if not hundreds, of acres annually. Grub at the roots or within the bark, the injury done by cattle and sheep, opossums destroying persistently the young shoots, and various other pests, have been set down as the cause, but no explanation has as yet been accepted as satisfactory. It would seem rather as if the trees were suffering from some sickness such as animals are subject to, and many square miles of bush may be cleared away before the disease has spent itself.

Whatever may be the cause, the trees are rapidly disappearing within the drainage area of the lake, and the result will be that with improved drainage and less absorption the lake *must* increase in extent during the next few years, provided the rainfall does not seriously diminish during the same period. Another cause which has probably been at work in enlarging the lake during the last twenty-four years, is an increased rainfall; but the argument on this point is rather drawn from the rapid growth of the lake than from any accurate observation. It has certainly happened once or twice during dry seasons that the lake has fallen a foot or two, but it has always recovered and advanced during the following year, so that its growth may be considered to have been continuous since the year 1852. After the winter of 1874, the lake rose from four to five feet, and during the severe drought of the following summer sank to the extent of from one to two feet, but with the returning rains it recovered its former level. If, up to the present time, the first and wet half of a cycle has been operating, and twenty-five years of deficient rainfall were now to commence, it would still, I think, be unreasonable to expect that the lake would contract very much—say to one half or one quarter its present size. The water that falls at the most distant spot in the basin is carried within a few hours into the lake—in the same manner as in other parts of the country it is carried into the rivers; and the same cause which tends to make the floods of the Hunter and other rivers more violent every year, will prevent Lake George from ever again becoming an insignificant pool. It may be noticed that cloudy summers—not necessarily rainy ones—would have a considerable effect in diminishing evaporation and thereby preventing shrinkage. A prevalence of westerly or northerly winds would have an opposite effect.

Near one of the squatters' houses, long ago submerged, was a well-stocked fish-pond. This the advancing waters soon appropriated, and its occupants finding their way into the lake, have increased to such an extent that the lake itself is now well stocked. These fish were chiefly the freshwater cod of Australian streams, and some of them have thriven so well that it is by no means rare to meet with specimens weighing from thirty to forty pounds each. Black swans, large flocks of three or four different kinds of ducks, with the red legged ibis and other birds frequent the shores and afford good sport.

The general appearance of the lake shore is somewhat desolate on account of the enormous number of partially submerged trees that stand, some of them a mile or more out in the water, and give the lake the appearance of an American river during a flood. The Eastern shore, however, is very beautiful for Australian scenery, the hills dotted with clumps of dark casuarina rising in beautiful grassy slopes from the water's edge.

At a few miles distance from Lake George to the eastward is Lake Bathurst, a much smaller sheet of water that appears to be under very much the same influences as the larger lake, the encroachment of the water being as well marked, although not so extensive.

It would be interesting to know all the influences at work in the increase of the Great Salt Lake, Utah, which is said to be growing at the rate of ten inches in vertical height yearly. As the whole country in the neighbourhood of this lake is destitute of trees, a periodic increase of rainfall is most probably the chief cause, in which case the lake's maximum may be expected to be reached at any time.

The cultivation of land previously bare might naturally be expected to cause a greater retention of moisture, whilst at the same time the hardening of the surface by the treading of cattle and sheep would cause the water to run off more easily; but the area of cultivated or pastured land within the drainage basin compared with that left in its primitive condition, is unknown, and it would be impossible to differentiate their effects.

It will be a subject of considerable interest to watch the conduct of the lakes during the next twenty years. R. ALBAY

The Cruise of the *Argo*

MANY useful suggestions were forwarded to me by the readers of NATURE before the yacht left Liverpool, in return for which I send my best thanks and a list of the places we have visited in the course of our most delightful and, as I trust, not unsuccessful voyage. Jan. 24, Madeira; Feb. 7, Antigua; Feb. 12, Barbuda; Feb. 13, St. Kitts; Feb. 14, Guadeloupe; Feb. 15, Dominica; Feb. 17, Martinique; Feb. 18, St. Vincent; Feb. 20, Grenada; Feb. 22, Trinidad; March 9, La Guayra; March 10, Caracas; March 17, Valentia; March 18, Puerto Caballo; March 21, Curaçao; March 27, Santa Marta; March 29, Savanilla; March 31, Carthagena; April 2, Kingston, Jamaica; April 13, Havana (Museum most creditable). We leave tomorrow for Vera Cruz and the city of Mexico, with the Bahamas, Philadelphia, New York, and Niagara in prospect. We have had a clean bill of health and favourable weather throughout. One of the chief objects proposed by Mr. Cholmondeley in undertaking the voyage was to observe the habits of tropical birds in the west, and to increase his fine collection in the aviaries at Condover. Amongst the very numerous specimens of birds now on board are some that are extremely fine, and such as have rarely been brought to England in a living state.

In marine collecting most has been done in sponges, tunicates, and echinoderms. These, which have been gathered amply and in the rough, will no doubt on examination yield some good microscopic forms, and perhaps a few polyzoa, of which there has been to me a most deplorable scarcity. In botanising, very fair success has been met with in Mosses, Lichens, and Fungi mainly. A few most interesting fungi were collected in the deep forest in Trinidad. Entomology has not been neglected, but the extreme dryness of the season has been unfavourable. Of the eminent men, true students of nature, it has been my good fortune to meet, I must not now attempt to mention even the names. My great obligation to them will I trust find a suitable opportunity for acknowledgment. HENRY H. HIGGINS

Havana, April 10

Recent Discoveries in New Guinea, and Papua or Papooa?

THE ascent for ninety miles of a fine river in the south-east portion of New Guinea in September last, by the mission vessel *Ellengowan* has doubtless before now been made known in England (NATURE, vol. xiii. p. 76).

I expect, during the present year, to leave Samoa on my return to England, and I have some hope that I may take New Guinea on my way to Australia, and visit the mission stations of the London Missionary Society on the south-east coast. If this hope is realised, I shall use every available means to determine what this large quadruped is, which has been tracked in three different parts of the island, if no one else makes the discovery before then.[1]

In concluding this letter, I wish to enter a protest against Dr. A. B. Meyer's orthography of the Malay names of New Guinea and the frizzly-haired portion of its inhabitants. He says (NATURE, vol. ix. p. 77 *note*) "I write Papooa, and not Papua, because the Malays pronounce the word Papooa and not Papua." Surely Dr. Meyer must be aware that the vowel *u* in Malay is pronounced like *oo* in English. As early as 1812 Marsden, in his Malay Grammar (p. 12), gives as examples of the sound of *u* the 'English *oo* in loom and tool.'" It appears to me not only pedantic and unnecessary, but also very objectionable, to make a change at the present time. Perhaps I feel more keenly on this point than most persons, owing to the fact that, with the assistance of a large staff of co-workers in various parts of the Pacific, I have in progress a comparative grammar

[1] It has been recently announced in the *Sydney Herald* that Signor D'Albertis has identified the large bird with the red-necked hornbill, and the droppings as those of the cassowary.—ED.

and dictionary of all the principal Malayo-Polynesian dialects, and am trying to reduce the whole to a uniform system of orthography. S. J. WHITMEE

Samoa, Jan. 3

The Visible Horizon

A POINT of some scientific interest has just been argued in the High Court of Justice. It was contended by the Solicitor-General that the three miles' limit of territorial waters was of modern origin, and by Sir R. Phillimore that it was due to that being the distance a cannon ball would reach from the shore. There can, however, be no doubt that the limit was recognised long before the invention of gunpowder.

Three miles is the distance of the *offing* or visible horizon to a person six feet in height standing on the shore. It is natural to suppose that the early maritime peoples of Europe would lay claim to the sea as far as the eye could reach. This distance they would find by experience was just *three miles*, and it can be proved mathematically to be correct. Measured by this standard—a tall man, usually taken as six feet high—the distance is invariable for all time, places, and peoples; measured by a cannon ball, it is constantly varying, and now ought to be five miles rather than three. The fact that the distance depends on both ocular and mathematical demonstration, and is not subject to improvement in gunnery, is the best explanation of its origin and application. B. G. JENKINS

Dulwich, May 8

Lunar Maps

LOHRMAN'S complete map, three feet in diameter, four sections of which were published in 1824, has been recently engraved by J. A. Barth, of Leipzig, under the supervision of Dr. Schmidt, director of the Athens Observatory, who has contributed a descriptive letterpress.

Schmidt's own map of six French feet diameter, will be issued before the end of the present year, from the *atelier* of the Royal Prussian Staff, the Prussian Government having, with great credit to itself, purchased that incomparable work. It is the result of thirty-four years' labour, and contains about 34,000 craters and an equal number of hills, besides over 350 rills and other objects. The difficulty of noting and correctly mapping this amazing number of lunar formations will be understood by anyone at all acquainted with the subject; and it will be seen that Dr. Schmidt has completed an achievement not surpassed in scientific capability and perseverance. A written text will accompany the map.

It were to be wished that our own countryman, Mr. Birt, could look forward to a similar recognition of his services. His great lunar map, of which we have heard nothing for some time, is on a plan quite different from Schmidt's, to which it would be found, if completed, an invaluable accompaniment by observers of the lunar surface; and it will speak but little for the scientific taste of our country if Mr. Birt's work is allowed finally to collapse for want of appreciation and encouragement.

Millbrook, Tuam, Ireland J. BIRMINGHAM

OUR ASTRONOMICAL

THE STAR-LALANDE 27095 (BOOTES).—Olbers, writing to Bode in July, 1804, respecting his observations of the comet of that year, remarks of Lalande 27095, near the place of which star the comet was situated on March 22: "Ist nicht mehr am Himmel zu finden." It was observed by Lalande as a seventh magnitude, 1795, May 25 ("Histoire Céleste," p. 164), centre wire at 14h. 42m. 10s.

The star was observed by Bessel, 1828, May 24, as a 9th magnitude, and is No. 976 of Hour xiv. in Weisse's second catalogue. In the "Durchmusterung" it is 9·0. There is evidently reason for supposing the star to be variable.

It follows the sixth-magnitude-star B.A.C. 4906, 19s., and is 6′ 37″ north of it, the position for the beginning of the present year being R.A. 14h. 45m. 56s., N.P.D. 52° 6′·5.

THE FIRST COMET OF 1743.—Notwithstanding the very marked deviation of the orbit of this comet from a parabola, it does not appear that any attempt has yet been made to determine, directly from the observations, the true form of the orbit, or at any rate to work out elements which will satisfy the observations within their probable limits of error. It is true that these observations, with one or two exceptions, are by no means exact, and Olbers, who examined the question in 1823, was of opinion that, from their general uncertainty, an investigation into the nature of the conic section described was hardly worth the trouble it would involve. Notwithstanding this expression of opinion from so high an authority, it may be remarked that there are a sufficient number of observations in our possession which cannot fairly be supposed liable to serious errors to justify an attempt to deduce more satisfactory elements than those hitherto calculated.

The comet appears to have been first observed by Grischow or Grisso, at Berlin, on February 10, and his observation on the evening of that day was considered by Olbers to be the most certain of any he made upon this comet, and not liable to a greater error than 2′ or 3′. On February 14, 15, 16 and 19, Grischow, observing apparently with Margareta Kirch, also gives particulars from which probably fair positions might be deduced. And we have an observation by Father Frantz, of Vienna, on February 21, given in proper form in the "Philosophical Transactions" of the Royal Society. Also a good observation by Maraldi at Paris on February 13, and one by Cassini on February 17, which last, however, is open to some doubt, not only for a reason pointed out by Olbers, but from an error as to the comparison star. Zanotti's observations at Bologna, form the longest series, and extend from February 12 to 28, but they are only published (in *Mémoires de l'Académie*, 1743) in longitude and latitude to minutes of arc, without further detail, and were not given by Zanotti as having any pretensions to accuracy. The parabolic orbit with which Olbers was content to discontinue his computations was the following:—

Perihelion Passage, 1743, Jan. 10, at 20h. 29m. 37s. Paris M.T.

Longitude of perihelion .	92 57 51	
,, ,, ascending node .	67 31 57	
Inclination to ecliptic . .	2 10	
Perihelion distance	0·83818	(Earth's mean distance 1)

These elements agree well, according to Olbers, with the positions observed on Feb. 10 and 28, and with the longitudes on Feb. 13 and 21, but the latitudes on these days differ by 14′ and 10′ respectively, which is precisely the kind of discordance, which we might expect to find, if the true orbit of the comet were an ellipse of short period. It will be remembered that Clausen considered this comet identical with that of November 1819, detected by Blanpain at Marseilles, with a period of 6·73 years before 1758 and 5·60 years after 1817, and that at the suggestion of Olbers the perturbations were calculated at the Collegio Romano to the year 1836, when the comet had been expected to re-appear. The orbit of short period which appears in catalogues with Clausen's name, was calculated from Zanotti's observations of Feb. 12, 20, and 28, with a pre-supposition as to the length of the major-axis. As already remarked, no attempt, so far as we know, has yet been made to deduce elements direct from the observations, which shall represent them with smaller errors than the parabolic orbits of Lacaille, Olbers, and Struyck.

Grischow records that on the evening of Feb. 11, 1743, the apparent diameter of the comet was 18′, that it appeared like a greyish-white cloud, but with close attention, "ein kleines helles Punctlein in der Mitte gewahr." We find by calculation that the comet at this time was distant from the earth only 0·051 of the earth's mean distance from the sun, and are reminded that such an object would have afforded an opportunity of the kind to which Mr. Marth has lately adverted, for a determination of the amount of solar parallax. A similar opportunity

may recur at any time, and, as is most probable, very suddenly; we can only hope that observers will be equal to the next occasion.

THE MINOR PLANETS.—Of the members of this group, in addition to the four older ones, Ceres, Pallas, Juno, and Vesta, at present favourably placed for observation, the brighter are Hera, Iris, and Melpomene; Hera and Melpomene are a little below the tenth magnitude, and Iris about 9·5. The following are approximate positions for Greenwich midnight:—

	Hera. R.A.	Hera. N.P.D.	Iris R.A.	Iris N.P.D.	Melpomene. R.A.	Melpomene. N.P.D.

THE GREENWICH TIME SIGNAL SYSTEM

IN NATURE for April 1 of last year (vol. xi. p. 431) we gave a description of the new Sidereal Standard Clock of the Royal Observatory at Greenwich. Fundamentally important as is this clock in all that concerns its relation to exact astronomical science, it performs also another and more immediately practical duty, that of regulating the time of great part of the United Kingdom. And we propose now to trace the connection existing between this purely astronomical clock and those by which the daily business of our lives is arranged.

A few words of preliminary history may not be uninteresting. Formerly, when, comparatively speaking, little communication existed between the people of different towns, each place kept its own local time. But when railways began to be extended through the country in all directions, such manner of reckoning time could not with any regard to convenience be followed in arranging the movements of trains. The adoption of one uniform system of counting time having, as regards railways, thus become a necessity, all towns in connection with railways, as a matter of convenience, fell sooner or later into the same system, one now universally followed. The time of the meridian of Greenwich is that employed. This selection was probably in part accidental. The railway authorities, when seeking for uniformity, would naturally be led to take as standard the time of the most influential place, and so adopt metropolitan time, which happens to be, practically, Greenwich time. But however this may be, the selection was for another reason a happy one. The meridian of Greenwich is that from which longitudes are counted on all British maps, and Greenwich time having been already long used by the navigator, means of obtaining a proper knowledge of it at seaports was very desirable. Its adoption for railways by facilitating the after-introduction of the time-signal system as now existing was therefore a fortunate circumstance.

The regular exhibition of accurate time for public use, by any kind of authoritative signal, was commenced at Greenwich in the year 1833, when the first time-ball was erected on the eastern turret of the ancient portion of the Observatory buildings, principally for the purpose of giving Greenwich time to chronometer makers and seamen. It has been dropped every day since the year mentioned, excepting only during some periods of repair, and occasionally on days of violent wind. The ball, which is about five feet in diameter and painted black, is by mechanical means raised half-way up its mast at 5 min. before 1h. as a preparatory signal; at 3 min. before 1h. it is hoisted to the summit. It drops at 1h. true Greenwich mean solar time. Formerly it was discharged by an attendant who, watching a clock the error of which had been previously ascertained, pressed the ball-trigger at the proper instant, but since the year 1852 it has been discharged by automatic means, as will be explained further on. The first start of the ball, or its separation from the cross (indicating the cardinal points) immediately above, is very sudden, and is the phase to be noted; afterwards (to avoid injury to the building), a piston, connected by a long rod to the ball, falls into a nearly air-tight cylinder, and so checks its descent that it comes gently to rest at the foot of the mast.

Within a few years of the establishment of the Greenwich ball, others were erected at British observatories near to ports and harbours, as Edinburgh, Liverpool, Glasgow, &c., principally also for the service of shipping. And such signal balls or equivalent means of exhibiting time are now to be found at many observatories abroad, as for instance at the Cape of Good Hope, Madras, Bombay, Sydney, Melbourne, Mauritius, Quebec, Washington, &c. Originally such time-balls could only be dropped at an observatory or institution at which time was determined by celestial observation, but on the introduction of the electric telegraph an observatory could be made the centre of a system from which, by galvanic means, time-balls could be dropped at, or time-signals given to, distant points.

On the first establishment of the electric telegraph in England, the connection of the Royal Observatory with the telegraphic system and its possible application to the daily distribution of time throughout the kingdom soon engaged the attention of the Astronomer Royal, but before things had come to any definite shape, the scheme for laying a submarine cable between England and France was proposed, and active steps taken to carry it out. The progress of this work was watched with interest by astronomers on both sides of the channel, and some of the active members of the Institute of France having expressed their earnest desire to take advantage of the new cable for galvanic determination of the difference of longitude between the Observatories of Paris and Greenwich, the Astronomer Royal became enabled in the year 1852, principally with the assistance of Messrs. E. Clark (of the then existing Electric Telegraph Company) and C. V. Walker (of the South-Eastern Railway Company), to establish the long-desired communications on the English side. The application of the telegraph to the direct determination of longitude will not, however, further concern us at present. As soon as telegraphic connection with the Royal Observatory was complete, the system of transmitting time signals from Greenwich for distribution by the Electric Telegraph Company on their lines was commenced, special apparatus having been for the purpose prepared both at Greenwich and London. This we now proceed to describe.

The Mean Solar Standard Clock of the Royal Observatory, the principal clock of the whole time-signal system, erected in the year 1852 specially for the work, is always kept adjusted as nearly as possible to exact Greenwich mean time. It is a clock of Shepherd's construction, with seconds pendulum, and is maintained in action by galvanic means alone. But it works others sympathetically. The wire which carries the galvanic currents from the pendulum to the electro-magnets to drive the hands is continued, before returning to the battery, to other electro-magnets in connection with the hands of other dials in different parts of the Observatory building, so that the hands on all the dials advance simultaneously, the forward motion of the whole system depending entirely on the one pendulum of the standard clock. Of these various clocks, one is fixed in the boundary-wall of the Observatory; it is daily consulted by great numbers of people, and will be familiar to every visitor to Greenwich Park. Several are placed in the Chronometer Room for use in the daily comparison of the Royal Navy and other chronometers, the difference between the time shown on one of these dials and that of any chronometer giving immediately the error of the chronometer without further calculation. Other dials are to be found in different office rooms in which accurate time is necessary. All these

clocks, including a seconds' relay, *a*, in the accompanying sketch, are *driven* by the galvanic current, but the standard clock further *controls* (by seconds' beats passing to London on a special wire from the seconds' relay) other clocks in London, on a principle, introduced nearly twenty years ago by Mr. R. L. Jones, in which the galvanic force is used, not as the driving power, but as an auxiliary, to keep right clocks already going very nearly right, each by its own motive power. The principle has assumed various practical forms, but that proposed by Mr. Jones is generally employed, and is as follows :—The ordinary bob of the pendulum to be controlled being removed, a horizontal galvanic coil is substituted. At each swing of the pendulum the coil encircles permanent bar magnets fixed to the clock-case, and the galvanic current received at each second from the controlling clock circulates through the wire of the coil. Then (within certain rather wide limits), whether the clock to be controlled tends to lose or gain, the magnetic action produced between the coil and the permanent magnets at the instant of passage of the current so accelerates or retards the pendulum that the clock is maintained in perfect sympathy with the controlling clock.

Thus, at Greenwich various mean-time clocks within the Observatory, and several in London, depend on the one pendulum of the standard clock at Greenwich. But it is a condition that the clocks shall continue to show exact Greenwich time, and as no pendulum will perform with the necessary accuracy for any long period, it becomes essential to provide convenient means of making periodical correction. The plan used at Greenwich is as follows :—To the pendulum of the Mean Solar Standard is attached a slender bar magnet about five inches long, carried parallel to the rod by an arm projecting forwards from it. Immediately below, in a central and vertical position, and supported by the clock-case, is placed a hollow galvanic coil, the accelerating and retarding coil. The lower end of the magnet passes closely over the upper end of the coil. A galvanic current when passed through the coil imparts to it magnetic properties, reversion of the current reversing the direction of its magnetism. If the current be such as to cause attraction between the adjacent ends of the swinging magnet and fixed coil, the pendulum, carrying with it the whole system of clocks, will be accelerated ; an opposite current causing repulsion will conversely produce retardation. The only caution to be observed is that correction must not be made too rapidly, otherwise the controlled clocks,

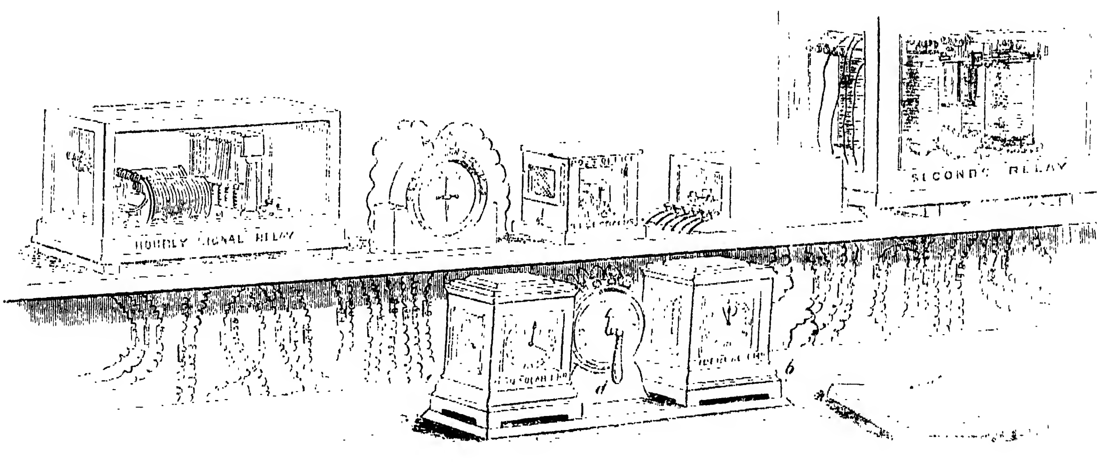

FIG. 1.—Time Signal Apparatus in the Computing Room at the Royal Observatory, Greenwich.

which are, as it were, merely *guided* by the controlling current, might, so to speak, break away from control. As at present arranged, to produce an acceleration or retardation of one second, the current must remain in action for about ten minutes.

Having described the mean-time system of clocks, and the magnetic appliance for correction of accumulated error, we have now to show how at any time the amount of correction required is determined. This makes it necessary to turn our attention to the system of sidereal clocks, and we shall now see how (as was stated at the beginning of this article) the Sidereal Standard is the real timekeeper of the country. This clock, with the system of sidereal clocks in connection therewith, was so fully described in the article already once referred to, that it will only be necessary to repeat here that amongst other things it galvanically registers its seconds on the paper of the revolving cylinder of the chronograph, and drives the sidereal chronometer *b*, situated on a certain desk in the Computing Room. Without going into further explanation it will be understood that, selecting a proper star of the *Nautical Almanac* list, the transit of which over the meridian has been observed with the transit circle and registered on the chronograph the times of its passing the several wires are extracted from the chronograph record, and the mean taken, which being corrected for the small errors of position of the instrument, and also (as the observations are taken by various observers) for "personal equation," the true clock-time of meridian passage, reduced to one standard, is found. The difference between this and the *Nautical Almanac* right ascension of the star for the day gives the error of the sidereal standard, which is also the error of the sidereal chronometer *b*. Unlike the mean-time clocks (which are required always to show true time), the error of the sidereal clocks is allowed to accumulate, and correction applied as necessary in any calculation in which time by one of the sidereal clocks enters.

Near to the sidereal chronometer *b* there is placed, on the same desk in the Computing Room, a mean solar chronometer, *c*, sympathetic with the Mean Solar Standard. Between these chronometers is fixed a commutator, *d*, by means of which a galvanic current can be thrown into the accelerating and retarding coil of the Mean Solar Standard. When the commutator index stands in the position shown in the drawing no action takes place ; when turned to the right the current accelerates the clock ; when turned to the left it retards the clock. To ascertain at any time the

moun[illegible] of correction required, the two chronometers are comp[illegible] by watching for a coincidence of beats [illegible] of the sidereal standard, by astro[illegible] described, the true sidereal time of c[illegible] becomes known the corresponding mean s[illegible] is then easily calculated, and the error of the [illegible] system of clocks immediately found The [illegible] handle is then turned to throw a battery current into the [illegible] and retarding coil, such as will attract or rep[illegible] the pendulum magnet of the Mean So[illegible] Standard according as the clock is found to be [illegible] The Mean Solar Standard and the various clo[illegible] sympathy with it (those driven by it at Green[illegible] and those controlled by it at London) all receive the [illegible] correction, and are all brought to exact Greenwich mean time By the arrangement described it will be seen that the Superintendent of the Time Department can at [illegible] time refer the Mean Solar system of clocks to the [illegible] Standard and find and correct the error of the [illegible] Standard and the whole system of mean [illegible] whilst engaged in his ordinary office duties, and without moving from his position in the Computing Room [illegible] is usually made every morning before [illegible] (because at that hour an important distribution of time [illegible] place), and again before [illegible] (another important [illegible] as regards time signals) The correction required is usually only a small fraction of a second

[illegible] shown how the error of the Sidereal Standard [illegible] is found by astronomical observation [illegible] the Mean [illegible] Standard, and [illegible] time, [illegible] proceed to describe the arrangements for giving time signals to the external world [illegible] circuit [illegible] through the Mean Solar Standard, but is broken in the clock in two places, one of these is united from about half a minute before to about half a minute after the minute hand marks sixty, and the other when [illegible] hand indicates sixty seconds precisely Both [illegible] therefore only be together united at the com[illegible] each hour, and then only can a current [illegible] hourly current [illegible] two electro[illegible] automatically discharges the Green[illegible] the other is [illegible] hourly signal relay (shown to the left in the [illegible] which completes various independent circuits, each [illegible] separate line of wire One of th[illegible] communication with the central telegraph [illegible] General Post Office, London another [illegible] to the London Bridge Station of the South [illegible] Company Along each line [illegible] time [illegible] Observatory [illegible] the control [illegible] point (excepting in the case [illegible] the sp[illegible] terminates The small [illegible] in the drawing marked [illegible] Hourly [illegible] Observatory, the position of the [illegible]

(To be continued)

THE OPENING OF THE LOAN COLLECTION

THE Loan Collection was auspiciously opened on [illegible] the visit of the Queen, and that [illegible] sufficiently shown [illegible] press, which we have [illegible] Queen's visit [illegible] complete su[illegible] Empress of Germany, [illegible] who accom[illegible] interest in the collec[illegible] and especially in those apparatus to which their attention was particularly drawn The *Times* is "authorised to say that not only did her Majesty express to the Lord President of the Council, the Duke of Richmond, her gratification with the exhibition and with its success —exceeding any that could possibly have been antici pated of it—but that her Majesty desired to make known how much she was gratified by the manner of her reception and by the solicitude with which her visit was made interesting by the several scientific men who explained to her the nature of the objects exhibited"

Besides the German Empress, the Queen was accompanied by the Princess Beatrice, the Duke of Edinburgh, the Duke of Cambridge, Prince Edward of Saxe Weimar, and among others who accompanied the Royal party during their tour round the collection were the Duke of Sutherland, the German, Austrian, Russian, and French and Spanish Ambassadors, the Italian Minister, the United States Chargé d'Affaires, besides a considerable number of the most eminent representatives of British and Foreign science, most of the members of the several committees, and many of the exhibitors

The Queen was received at the south eastern entrance to the Exhibition by the Duke of Richmond and Gordon and the Vice President of the Committee of Council on Education, Lord Sandon, M P, by the Commissioners of the Exhibition of 1851 upon whose premises the Exhibition is held, and by the members of the Duke of Devonshire's Committee on Scientific Instruction

The Duke of Richmond and Gordon escorted the Queen round the Exhibition, pointing out objects of interest, and as the Queen entered each division of the galleries, gentlemen conversant with the various branches of science had the honour of being presented and of explaining to their Majesties and Highnesses the objects exhibited

The Educational Collection was first examined, M Heard showing the curious and extensive Russian pedagogical collection In the Mechanical Section the famous primitive locomotives "Puffing Billy" and the "Rocket" attracted considerable attention In this section also the ship *Faraday* was described by Dr C W Siemens, who at the same time explained his bathometer, recently described in NATURE The German ironclad, *König Wilhelm*, and other beautiful models illustrating the applications of science to shipbuilding, including a model of the *Serapis*, were described by Mr E J Reed and the Duke of Edinburgh In this same section Mr W Froude showed his models of the hulls of ships in solid paraffin, by which the valuable experiments were made which were recently described by him at length in NATURE Prof Tyndall's explanation of the lighthouses and fog horns excited considerable interest the Siren fog horn being sounded to illustrate the usefulness of the signal In the Fish Museum Mr Frank Buckland was ready to explain the many interesting objects and processes shown there As the party passed into the gallery of Electricity and Magnetism, the enharmonic organ of Peronnet Thomson was heard from above playing "God save the Queen" In the section just mentioned M Breguet, of Paris, gave a brilliant display of the electric light, while Prof Carey Foster explained the great Haarlem natural magnet Mr Gramme's magneto electric machines were shown by Mr Spottiswoode, and various telegraphic instruments by Mr Culley As her Majesty proceeded leisurely through the collection, Sir William Thomson showed his wonderfully ingenious tide calculating machine, Joule's apparatus for researches in heat, and an apparatus for deep sea soundings Prof Kennedy exhibited the important collection of kinematic models sent by Prof. Reuleaux, of the Royal Technical Academy, Berlin. The Wilter type composing machine was explained by Mr J C Macdonald, Sir Joseph Whitworth described his millionth of an inch measuring apparatus, while Mr Chisholm explained various standard measures, a fine collection of standards made for the Russian Govern

ment by Dr. Werner Siemens, being particularly observed. The Astronomer Royal, Sir George Airy, showed the telescopes of Sir W. Herschel and Lord Rosse, and a little telescope of Newton's.

Prof. Eccher exhibited some interesting memorials of Galileo, his bust, telescope with broken lens, and other objects, invaluable relics, which the Queen expressed her gratification to see generously confided to the care of this Department of her Government by Signor Peruzzi, the Syndic, and the City of Florence. Mr. John Evans, in the Geological Department, exhibited results of the Sub-Wealden boring; and in the spacious gallery and conference room devoted on Saturday to Geography, Sir Henry Rawlinson showed the Queen Livingstone's maps, and illustrated the route of Lieut. Cameron; Lieut. Cameron himself exhibited his charts of the interior of Africa. Capt. Evans, the Hydrographer of the Navy, showed the original logs of Captain Cook and the log of the *Bounty*, and Admiral Ommanney a log of Sir John Franklin. A collection of German maps, explained by Major von Vistinghoff, and the interesting collection of fossil leaves shown by Baron von Ettinghausen, of Graetz were also inspected. In the Biological Department Prof. Burdon Sanderson and Dr. Lauder Brunton showed Marey's and other apparatus for recording and registering vital motion, and the instrument of Prof. Donders, of Utrecht, for measuring the velocity of thought. The musical instruments explained by Mr. J. Baillie Hamilton naturally attracted much attention. The other objects which attracted the attention of and were explained to the Queen and her party were Dalton's apparatus by Prof. Roscoe, Cavendish's and Black's balances by Dr. Frankland, early photographs by Capt. Abney, Russian heliographic plates and engravings by Baron von Wrangell, spectroscopes and radiometers by Prof. Guthrie, Otto von Guericke's air-pump and the Magdeburg hemispheres by Prof. Clerk Maxwell.

Before leaving the galleries, a telegram was despatched through one of the Morse instruments exhibited by our Post Office by the Empress Augusta of Germany, in the name of the Queen and herself, to the German Emperor in the following words: "The Queen and the Empress have passed through the collection at the Exhibition of Scientific Apparatus and have been very much interested." Her Majesty the Queen desired that the same intelligence should be communicated to her eldest daughter the Crown Princess.

To quote the *Daily News*:

"Throughout the course of the long promenade from the south-eastern entrance of the building in Exhibition-road to the exit in the Prince Albert's-road, neither the Queen nor the Empress of Germany exhibited the slightest sign of physical or mental fatigue. On the contrary, their majesties seemed rather inclined to remain for a space in converse with the learned expositors than to treat the inspection as a matter of ceremony."

During the visit, Sir Francis Sandford, Major Donnelly, Mr. Cunliffe Owen, and Mr. Norman Lockyer, were specially introduced to the Queen and Empress.

The Collection was opened to the public on Monday, and the number of visitors has been much greater than most people expected. They belong to all classes, and inspect the apparatus with evident interest and intelligence. The galleries, indeed, bear quite a lively aspect, and there is little danger of the Collection being a failure for lack of a public. We have no doubt, as its value and nature become known, the number of visitors will largely increase.

The first of the Conferences in connection with the Collection was opened on Tuesday, Lord Sandon making a short address of welcome.

"I have come down," he said, "to express my gratitude, and that of Her Majesty's Government, to the different men of science who are the real authors of what I may call the present success. I have had means of knowing personally the extraordinary sacrifices of time and labour of those men of science in this country who have produced the success. It is gratifying, if only for one reason—it has shown what a feeling of intellectual brotherhood exists. We have had the highest men of science of this kingdom working together to produce this very remarkable exhibition. When we think of their zeal and self-sacrifice and determination, the country cannot be too grateful. And these qualities have not been confined to this country, but far beyond this island. It has been a matter of universal remark, the zeal, the determination, and friendly feeling which have been shown by men of science all over the world. We have—the Lord President and myself—done all that we could do to make this not a gazing place merely, but to give as much instruction as possible to those who desire to receive it. These Conferences will be a source of the greatest possible gratification, old friendships will be renewed, new friendships will be created between men of science of other parts of the world. These Conferences will, we trust, be much appreciated. The examination of the collections will be much assisted by the admirable handbooks which have been prepared by men of the highest capacity. Allow me also to express my sense of the very high service which the officers of the Science Department have rendered; their zeal, their highly cultivated intelligence, devotion of time and almost of health—we have reason to be proud of serving the Queen in concert with such officers. To the different men of science I express my hearty good wishes for exertions towards the continued success of the Exhibition. When those Conferences come to a close we shall feel that a great work has been done on behalf, not of this country only, but for the whole of the world."

Mr. Spottiswoode, the President of the Section of Physics, to which Tuesday was devoted, then delivered his inaugural address, which we are glad to be able to give below, as also that of Dr. C. W. Siemens, the President of the Section of Mechanics, which met on Wednesday. The other addresses on Monday were by Mr. W. Huggins, D.C.L., F.R.S., on the present state of Spectroscopic research relating to the Stars and Nebulæ; Mr Norman Lockyer, F.R.S., and Capt. W. de W. Abney, R.E., on Spectroscopic Research in Solar and Molecular Physics; M. le Professeur Soret, on a Spectroscope with a fluorescent eye-piece; Prof. R. Bellamy Clifton, M.A., F.R.S., on Interference, and Instruments for the measurement of Optical Wave Lengths; Mr. H. C. Sorby, F.R.S., on the original form of the Spectrum-microscope, and the various subsequent improvements, and additional apparatus; the Earl of Rosse, D.C.L., F.R.S, on Zollner's Photometer; Prof. Sir W. Thomson, LL.D., F.R.S., on the principles of Compass Correction in Iron Ships; M. Sarasin-Diodati, on De la Rive's Researches in Statical Electricity; and the President, on some recent forms of Polariscopic Apparatus.

In the Section of Mechanics, which met yesterday, besides the address of the President, Dr. Siemens, the following papers were read:—

Sir Joseph Whitworth, Bart., F.R.S., on Linear Measure; Mr. C. W. Merrifield, F.R.S., on Solid Measurement; followed by a communication from Prof. Tilser (Bohemian Institute, Prague); Prof. Sir W. Thomson, LL.D., F.R.S., on Electrical Measurements; M. Tresca (Sous-Directeur du Conservatoire des Arts et Métiers, Paris), on Flow of Solids; Prof. Kennedy, on Kinematics, &c.

The Chemical Section meets to-day, when, after the address of the President, Prof. Frankland, the following papers will be read:

Dr. J. H. Gilbert, F.R.S, on some points in connection with Vegetation; Mr. W. F. Donkin, M.A., of Keble College, Oxford, on the Ozone Apparatus of Sir B. Brodie, Bart., F.R.S.; Mr. A. Fletcher, H. M. Inspector of Alkali Works, on the Gases discharged from Alkali Works; Professor Andrews, F.R.S., Experiments on Gases.

On the 19th and 24th the Section of Physics will again meet; Mechanics on the 22nd and 25th; Chemistry on the 23rd; Biology on the 26th and 29th; and Physical Geography, Geology, Mineralogy, and Meteorology on May 30 and June 1 and 2.

The following are the arrangements which have been made in the Section of Mechanics:—22nd May.—Mr. Barnaby, C.B., Director of Naval Construction to the Admiralty, Naval Architecture; Mr. W. Froude, M.A., F.R.S., Fluid Resistance; Mr. Thomas Stevenson, Lighthouses. 25th May.—Mr. F. J. Bramwell, F.R.S., Prime Movers; Mr. Hackney, B.Sc., Furnaces; Général Morin, Directeur du Conservatoire des Arts et Métiers, Paris, Ventilation; Professor Zetzsche, Electric Telegraphs.

A general idea of the arrangements in other sections will be obtained from the list in last week's NATURE, p. 34.

Besides these Sectional Meetings, several *soirées* have been arranged, the first of which, that of Physics, took place last night. A Geographical *soirée* will be held on Saturday night.

Several visits have, moreover, we believe, been arranged, including one to H. M. S. *Challenger*, which is expected home every day.

The following are the names of some of the distinguished foreigners who have come to London in connection with the Loan Collection:—*Germany:* Dr. R. Schone, Herr Wilhelm Kirchner, Dr. Biedermann, Dr. Neumayer, W. Verners, C. Desaga, Herr Lingke, M. Borus, Dr. Julius Fettbach, Dr. H. Rohrbeck.—*Russia:* Baron von M. Wrangell, M. Heard, Dr. Selim Lemström, Capt. M. Rkeman, R.A., M Ovsiannikow, Prof. A. von Oettingen. —*Italy:* Il Com. Blaserna, Prof. De Eccher, Cav Meucci. —*Austria:* Baron von Ettinghausen, Dr. Albert von Ettinghausen, Dr. Leopold Pfaundler.—*Holland:* Prof. Dr. P. L. Rijke, Dr. J. W. Gunning, Dr. D. de Loos, Prof. Dr. J. Bosscha.—*Switzerland:* M. Soret, M. Hagenbach, M. Forel, M. Wartmann, Prof. Favre, M. E. Gautier, M. Th. Turrettini, M. E. Sarasin, Prof. E. Hagenbach-Bischoff, M. R. Pictet.—*Belgium:* A. Renard, Prof. C. de la Vallée Poussin, Prof. G. Dewalque.—*Spain:* Señor Juan E. Riaño,.—*Orange Free State:* His Honour, the President of the Orange Free State.—*France:* M. Tresca, M. Golaz, M. Breguet, P. Jablochkoff.—*Norway:* Prof. P. Waage.—*Sweden:* Dr. Christian Lovén.

SECTION—PHYSICS.

Opening Address by W. Spottiswoode, F.R.S., &c.

THE opening of this Exhibition may prove an epoch in the science of Great Britain. We find here collected, for the first time within the walls of one building, a large number of the most remarkable instruments, gathered from all parts of the civilised world, and from almost every period of scientific research. These instruments, it must be remembered, are not merely masterpieces of constructive skill, but are the visible expression of the penetrative thought, the mechanical equivalent of the intellectual processes of the great minds whose outcome they are.

There have been in former years, both in this country and elsewhere, exhibitions including some of the then newest inventions of the day; but none have been so exclusively devoted to scientific objects, nor any so extensive in their range as this. There exist in most seats of learning museums of instruments accumulated from the laboratories in which the professors have worked; but these are, by their very nature, confined to local traditions. The present one is, I believe, the first serious, or at all events the first successful, attempt at a cosmopolitan collection.

To mention only a few, among the many foreign institutions which have contributed to this undertaking, we are especially indebted to the authorities of the Conservatoire des Arts et Métiers of Paris, the Physical Museum of Leyden, the Tayler Foundation of Haarlem, the Royal Museum of Berlin, the Physical Observatory of St. Petersburgh, the Tribune of Florence, and the University of Rome.

Among those in our own country, we have to thank the Royal Society, the Royal Institution, the Ordnance Survey, the Post Office, the Royal Mint, the Kew Observatory, besides various other institutions and colleges, which have freely contributed their quota.

To enumerate even the chief of the individual instruments of historical interest would be a task beyond the limits both of my powers and of your patience. But I cannot refrain from naming as especially worth notice among the astronomical treasures, a quadrant of Tycho Brahé, telescopes of Galileo, a telescope of Newton, some lenses by Huygens, one of Sir W. Herschel's grinding machines for specula, and a telescope made by himself in intervals between his music lessons during his early days at Bath, at a time when, to use her own words, his sister Caroline "was continually obliged to feed him by putting victuals by bits into his mouth." This also is probably the "mirror from which he did not take his hands for sixteen hours together," and with which he may have seen for the first time the Georgium Sidus. To come to later days, we have the original siderostat of Foucault, lent from the Observatory of Paris, a compound speculum by the late Lord Rosse, the photoheliograph from Kew, and from still more recent times a complete transit of Venus equipment, from the Royal Observatory at Greenwich.

Turning to other branches of physics, we have a "composed microscope," now nearly three centuries old, constructed in 1590 by one Zacharias Janssen, a spectacle-maker, possibly a connection, or at all events a worthy predecessor, of M. Janssen, the celebrated astronomical spectroscopist. We have an air-pump, and two "Magdeburg hemispheres," with the original rope traces by which horses were attached in the presence of the Emperor Charles V., in order, if possible, to tear them asunder, when exhausted by the air-pump. We have the air-pump of Boyle, the compressor of Pappin, Regnault's apparatus for determining the specific heat of gases, Dumas's globe for the determination of vapour densities, Fizeau and Foucault's original revolving mirrors and toothed wheels, whereby the velocity of light was first determined independently of astronomical aid, Daguerre's first photograph on glass, and the earliest astronomical photographs ever taken. To these may be added De la Rive's instruments for statical electricity; the actual table and appurtenances at which Ampère worked; and some contrivances as if fresh from the hands of Faraday himself.

Yet rich as is this part of our collection, and interesting as it might be made in the hands of one versed in the history and anecdote of the past, we must not linger even about these pleasant places. Indeed a museum of only the past, venerable though it might be, would be also grey with the melancholy of departing life. For science should be living, instinct with vigour and organic growth. Without a continuance into the present, and a promise for the future, it would be like a tree whose branches are broken, whose growth is stopped, and whose sap is dried. And if I may carry the simile a stage further, an exhibition of the present, with no elements of the past, would be like the gathered fruits to be found in the market-place, ready to hand, it is true, but artificially arranged. But when past and present are represented in combination, as has been attempted here, the very newest achievements will be found in their natural places as ripened and ever-ripening fruit in the garden from whence they have sprung.

In reviewing the series of ancient, or at least now disused, instruments, one thing can hardly fail to strike the attention of those who are accustomed to the use of the

modern forms. It is this—how much our predecessors managed to achieve with the limited means at their disposal. If we compare the magnificent telescopes, the exquisite clockwork, the multiplicity of optical appliances, now to be found in almost every private, and still more in every public, observatory, with those of two centuries past; or, again, if we look at the instruments with which Arago and Brewster made their magnificent discoveries in polarised light, in contrast to those with which the adjoining room is literally teeming, we may well pause to reflect how much of their discoveries was due to the men themselves, and how comparatively little to the instruments at their command.

And yet we must not measure either the men or their results by this standard alone. The character of the problems which nature propounds, or which our predecessors leave as a legacy to our generation, varies greatly from time to time. First, we have some great striking question, the very conception and statement of which demands the very highest powers of the human mind; unless, indeed, the clear and distinct statement of every problem may be regarded as the first and most important step towards its solution. Next follow the first outlines of the solution sketched in bold outline by some master hand; afterwards, the careful and often tedious working out of the details of the problem, the numerical evaluation of the constants involved, and the reduction of all the quantities to strict measurement. It is in this part of the business that the more elaborate instruments are especially required. It is for bringing small differences to actual measurement, for detecting quantities otherwise inappreciable, that the complex refinements with which we are here surrounded become of the first importance. But happily this somewhat overwhelming complication is not of perennial growth, for, curiously enough, by a kind of natural compensation, it relieves itself. In reviewing from time to time the various aspects of a problem in connection with the instrumental appliances designed for its solution, the essential features come out by degrees more strongly in relief. One by one the unimportant parts are cast aside, and the apparatus becomes reduced to its essential elements. This simplification of parts, this cutting off of redundancies, must not, however, be understood as detracting from the merit of the original devisors of the instruments so simplified; the first grand requisite is to effect what is necessary for the solution of the problem, then follows the question whether it can be done more simply or by some better process.

And this leads me in the next place to advert for a moment to the advantages which may accrue to the cultivators of science, and through them to the nation at large, from a national collection of scientific apparatus. Through the liberality of our foreign neighbours, and through the exertions of our own countrymen, we have here a magnificent specimen, an almost ideal exemplar, of what such a collection may be. By bringing together in one place, and by rendering accessible to men of science generally, the instrumental treasures already accumulated, and constantly accumulating, we should not only portray in, as it were, living colours the history of science, we should not only be paying just tribute to the memory of the great men who have gone before us, but we should afford opportunities of reverting to old lines of thought, of repeating with the identical instruments important but half-forgotten experiments, of weaving together threads of scattered researches, which could otherwise be taken up again only with difficulty, and after an expenditure of much and irretrievable time.

Let me now turn for a moment to the other side of the picture. If the collection in the midst of which we are here assembled is an evidence of the valuable relics which still remain to us of the great men who have passed away, the circumstances under which some of them have found their way hither, and the vacant places due to the absence of others, are no less evidence of how much the preservation of such objects would be promoted by the establishment of a museum such as I have ventured to suggest. Many circumstances contribute to thrust into oblivion, or to put absolutely out of reach of future recovery, original apparatus. First, the paramount importance and immediate uses of an improved instrument or a new invention; next, in Government departments such as the Survey, the Post Office, &c., the imperative demands of the public service, which leave little or no time for a retrospect of the past; and if I may add a word from the experience of private individuals, the pressing calls of space and expense lead the possessors to throw away, or to utilise, by conversion of the materials to new purposes, apparatus which has done its work. I venture to particularise one or two considerations, which will probably have occurred to many of you, but which appear to me to illustrate the above remarks. In the case of the Ordnance Survey it is almost certain that the current work of the department would never have required, and it is doubtful whether any private interposition would have brought about, the removal of the disused instruments, here exhibited, from the cellars at Southampton. Again, the Post Office would hardly have been justified in devoting valuable time to the arrangement, or valuable space to the storage, of instruments no longer on active service, except at the call of a public department, or for a public purpose. And surely it would be a matter of serious regret that the time already spent upon the collection now before us should have no issue beyond the purposes of the present exhibition. To take another instance; we have here fragments, but only fragments, of Baily's apparatus for repeating Cavendish's experiments; but of Cavendish's own apparatus we have simply nothing. Again, Wheatstone's instrumental remains must inevitably have been broken up and scattered or destroyed, if there had not been found at King's College a resting-place, and authorities intelligent enough to appreciate and willing to receive them. Of other individuals from whom apparatus, now of historical interest, has been received, some from sheer lack of space have been breaking up old instruments, while others, from a modesty commendable in itself, were with difficulty persuaded of, and even now are only beginning to perceive, the value, in a national and cosmopolitan point of view, of their own contributions. Lastly, there is, I think, little doubt but that, if the objects in question were to go a-begging, they would be gladly received in some of the foreign museums which have so liberally contributed on the present occasion.

To put the suggestion in a more tangible form I would venture to suggest that, in the first instance, instruments whose immediate use has gone by, but which are nevertheless of historical interest, lent either by public departments or by private individuals, might remain here on permanent loan; further, that other instruments as they pass out of active service, for example, from the Admiralty, from the Board of Trade, from the Ordnance Survey, or from the other departments, should similarly find a place in this museum. In such a category also might be included the scientific outfit of the *Challenger*, and of the Arctic Expeditions, and likewise those of expeditions for the observations of the transit of Venus or of solar eclipses. To these might be added apparatus purchased for special investigations through the parliamentary grant annually administered by the Royal Society. And further if, as I would suggest, this deposit of instruments be made without alienation of ownership, then private societies or even individuals might be glad to avail themselves of such a depository of instruments not actually in use.

In making such a suggestion, it must of course be assumed that the custody of property so valuable in itself, and so delicate in its nature, would be confided to a

curator thoroughly competent for such a charge, but I abstain from entering prematurely into further details.

And now let me turn in conclusion to one more aspect of this great undertaking. We have here collected not only the instruments which represent the most advanced posts of modern science, but we have not a few of the men whose genius and perseverance have led the way thither; men who stand in the forefront of our battle against ignorance and prejudice and against the host of evils which a better scientific education must certainly dispel; we have men whose powers are competent for, and whose very presence is an inspiration to, further progress. But, while taking this first opportunity of offering them a hearty welcome, I shall however best consult both their feelings and your wishes by abstaining from any panegyric upon them in their presence, and by giving them an opportunity of speaking, and you of hearing them, upon some of their own subjects in illustration of the remarkable instruments which they have with so much pains and trouble brought under our view.

SECTION—MECHANICS.

Opening Address by Dr. C. W. Siemens, F.R.S.

In opening the proceedings of the Conferences regarding Mechanical Science, it behoves me to draw attention to the lines of demarcation which separate us from other branches of natural science represented in this Exhibition.

In the Department of Applied Science we have collected here apparatus of vast historical interest, including the original steam cylinder constructed by Papin in 1690, the earliest steam-engines by Savery and by James Watt, the famous locomotive engine the "Rocket," by which George Stephenson achieved his early triumphs, as well as Bell's original marine engine, and a variety of models illustrative of the progress of hydraulic engineering and of machinery for the production of textile fabrics. In close proximity to these we find a collection of models illustrative of the remarkable advance in naval architecture which distinguishes the present day.

It would be impossible to deny the intrinsic interest attaching to such a collection or its intimate connection with the progress of pure science; for how could science have progressed at the rate evidenced in every branch of this Exhibition, but for the great power given to man through the mechanical inventions just referred to. Yet were Mechanical Science at these Conferences to be limited to the objects exhibited in the South Gallery (and separated unfortunately from apparatus representing physical science by lengthy corridors filled with objects of natural history), we should hardly find material worthy to occupy the time set apart for us. But, thanks to the progress of opinion in recent days, the barrier between pure and applied science may be considered as having no longer any existence in fact. We see around us practitioners, to whom seats of honour in the great academies and associations for the advancement of pure science are not withheld, and men who, having commenced with the cultivation of pure science, think it no longer a degradation to follow up its application to useful ends.

The geographical separation between applied science and physical science just referred to, must therefore be regarded only as accidental, and the subjects to be discussed in our section comprise a large proportion of the objects to be found within the rooms assigned more particularly to physics and chemistry. Thus all measuring instruments, geometric and kinematic apparatus, have been specially included within our range, and other objects such as telegraphic instruments, belong naturally to our domain.

With these accessions, mechanical science represents a vast field for discussion at these conferences, a field so vast indeed that it would have been impossible to discuss separately the merits of even the more remarkable of the exhibits belonging to it. It was necessary to combine exhibits of similar nature into subdivisions, and the Committee have asked gentlemen eminently acquainted with these branches to address you upon them in a comprehensive manner.

Thus they have secured the co-operation of Mr. Barnaby, the Director of Construction of the Navy, to address you on the subject of Naval Architecture, and of Mr. Froude to enlarge upon the subject of fluid resistance, upon which he has such an undoubted right to speak authoritatively. Mr. Thomas Stevenson, the Engineer of the Northern Lighthouses, will describe the modern arrangements of Dioptric lights, which mark a great progress in the art of lighting up our coasts. Mr. Bramwell has undertaken the important task of addressing you on the subject of Prime Movers, and Prof. Kennedy upon the kinematic apparatus forwarded by Prof. Reuleaux, of Berlin. M. Tresca will bring before us his interesting subject, the flow of solids. Mr. William Hackney will address you upon the application of heat to furnaces, for which he is well qualified both by his theoretical and practical knowledge. Mr. R. S. Culley, Chief Engineer of the Postal Telegraphs, will refer you to a most complete and interesting historical collection of instruments, revealing the rapid and surprising growth of the electric telegraph.

Measurement.—Regarding the question of measurement, this constitutes perhaps the largest and most varied subject in connection with the present Loan Exhibition. In mechanical science, accurate measurement is of such obvious importance, that no argument is needed to recommend the subject to your careful consideration. But it is not perhaps as generally admitted, that accurate measurement occupies a very important position with regard to science itself, and that many of the most brilliant discoveries may be traced back to the mechanical art of measuring. In support of this view I may here quote some pregnant remarks made by Sir William Thomson in his inaugural address delivered in 1871 to the members of the British Association, in which he says—"Accurate and minute measurement seems to the non-scientific imagination, a less lofty and dignified work than looking for something new. But nearly all the grandest discoveries of science have been but the rewards of accurate measurement and patient long-continued labour in the minute sifting of numerical results. The popular idea of Newton's grand discovery is that the theory of gravitation flashed upon his mind, and so the discovery was made. It was by a long train of mathemetical calculation, founded on results accumulated through prodigious toil of practical astronomers, that Newton first demonstrated the forces urging the planets towards the sun, determined the magnitude of those forces, and discovered that a force following the same law of variation with distance urges the moon towards the earth. *Then* first, we may suppose, came to him the idea of the *universality of gravitation;* but when he attempted to compare the magnitude of the force on the moon with the magnitude of the force of gravitation of a heavy body of equal mass at the earth's surface, he did not find the agreement which the law he was discovering required. Not for years after would he publish his discovery as made. It is recounted that, being present at a meeting of the Royal Society, he heard a paper read, describing geodesic measurement by Picard, which led to a serious correction of the previously accepted estimate of the earth's radius. This was what Newton required; he went home with the result, and commenced his calculations, but felt so much agitated, that he handed over the arithmetical work to a friend; then (and not when, sitting in a garden he saw an apple fall) did he ascertain that gravitation keeps the moon in her orbit.

Faraday's discovery of specific inductive capacity, which inaugurated *the* new philosophy, tending to discard

action at a distance, was the result of minute and accurate measurement of electric forces.

Joule's discovery of thermo-dynamic law, through the regions of electro-chemistry, electro-magnetism, and elasticity of gases, was based on a delicacy of thermometry which seemed impossible to some of the most distinguished chemists of the day.

Andrews's discovery of the continuity between the gaseous and liquid states was worked out by many years of laborious and minute measurement of phenomena scarcely sensible to the naked eye.

Here, then, we have a very full recognition of the importance of accurate measurement, by one who has a perfect right to speak authoritatively on such a subject. It may indeed be maintained that no accurate knowledge of any thing or any law in nature is possible, unless we possess a faculty of referring our results to some unit of measure, and that it might truly be said *to know is to measure*.

To resort to a homely illustration of this proposition, let us suppose a traveller in the unknown wilds of the interior of Africa, observing before him a number of elevations of the ground, not differing materially from one another in apparent magnitude. Without measuring apparatus the traveller could form no conclusion regarding the geographical importance of those visible objects, which might be mere hillocks at a moderate distance, or the domes of an elevated mountain range. In stepping his base line, however, and mounting his distance measurer, he soon ascertains his distances and observations with the sextant and compass, give the angles of elevation and position of the objects. He now knows that a mighty mountain chain stands before him, which must determine the direction of the watercourses and important climatic results. In short, through measurement he has achieved perhaps an important addition to our geographical knowledge. As regards modern astronomy, this may almost be defined as the art of measuring very distant objects, and this art has progressed proportionately with the perfection attained in the telescopes and recording instruments employed in its pursuit.

By the ancients the art of measuring length and volume was tolerably well understood, hence their relatively extraordinary advance in architecture and the plastic arts. We hear also of powerful mechanical contrivances which Archimedes employed for lifting and hurling heavy masses, and the books of Euclid constitute a lasting proof of their power of grappling with the laws regulating the proportion of plane and linear measurement. But with all the mental and mechanical power displayed in those works, it would seem strange that no attempt should have been made on the part of the ancients to utilise these subtle forces in nature, *heat* and *electricity*, by which modern civilisation has been distinguished, were it not for their want of the means of *measuring* these forces.

Hero of Alexandria tells us that the power of steam was known to the Egyptians, and was employed by their priesthood to work such pretended miracles, as that of the spontaneous opening of the doors of the temple whenever the burnt offering was accepted by the gods, or as we moderns would put it whenever the heat generated by combustion was sufficient to produce steam in the hollow body of the altar, and thus force water into buckets whose increasing weight, in descending, caused the gates in question to open.

Unfortunately for them, the Accademia del Cimento of Florence had not yet presented the world with the thermometer, nor had Torricelli shown how to measure elastic pressures, or there would at any rate have been a probability of those clear-headed ancients applying the power of steam for preparing and transporting the materials, which they used in the erection of their stupendous monuments, and for raising and directing the water used in their elaborate works of irrigation.

The art of measuring may be divided into the following principal groups:—

First. That of linear measurement, the measurement of area within a plane and of plane angles, comprising Geometry, Trigonometry, Surveying, and the construction of linear measures, distance meters, sextants, and plain meters, of which a great variety will be found within this building.

The subject of linear measurement will I am happy to state be brought before you by one whose name will ever be remembered as the introducer into applied mechanics of the absolute plane and of accurate measure, I mean Sir Joseph Whitworth. It is to be regretted I consider that Sir Joseph Whitworth adopted as the unit of measure, the decimalised inch instead of employing the centimetre, and I hope that he will see reason to adapt his admirable system of gauges also to metrical measure, which, notwithstanding any objections that could be raised against it on theoretical grounds—that, namely, of not representing accurately the ten millionth part of the distance from one of the earth's poles to the equator—is nevertheless the only measure that has been thoroughly decimalised, and which establishes a simple relationship between measures of length, of area and of capacity. It possesses moreover, the great practical advantage of having been adopted by nearly all the civilised nations of Europe and by scientific workers throughout the world. Sir Joseph Whitworth's gauges, based upon the decimalised inch are calculated to maintain their position for many years, owing to the intrinsic mechanical perfection which they represent, but the boon conferred by their author would be still greater than it is if by adopting the metre he would remove the last and only serious impediment in the way of the unification of linear measurement throughout the world. A discussion will probably arise regarding the relative merits of measurement *à bout* of which Sir Joseph Whitworth is the representative, and of measurement *à trait* which is the older method but is still maintained by the Standard Commissioners both in this country and in France.

The second group includes the measure of volume or the cubical content of solids, liquids, and gases, comprising stereometric methods of measurement, the standard measures for liquids, and the apparatus for measuring liquid and gaseous bodies flowing through pipes, such as gas meters, water meters, spirit meters, of which likewise a great variety of ancient and modern date will meet your eye, and upon which Mr. Merrifield will address you.

Another method of measuring matter is by its attraction towards the earth, or thirdly the measurement of weight represented by a great variety of balances of ancient and modern construction. These may be divided into *beam weighing machines* which appear to be at the same time the most ancient and the most accurate, into spring balances and torsion balances. The accuracy obtained in weighing is truly surprising when we see that a mass of one ten millionth part of a gramme suffices to turn the scale of a well constructed chemical balance. Perfect weighing, however, could only be accomplished in a vacuum, and, in accurate weighing, allowance has to be made for the weight of air displaced by the object under consideration. The general result is that the mass of light substances is really greater than their nominal weight implies, and this difference between true and nominal weight must vary sensibly with varying atmospheric density.

Weighing in a denser medium than atmospheric air, namely in water, leads us fourthly to the measurement of specific gravity which was originated by Archimedes when he determined the composition of King Hiero's crown by weighing it in water and in air.

Among measures of weight, may be noted a balance,

which weighs to the five-millionth part of the body weighed, sent by Beckers Sons of Rotterdam; another from Brussels weighing to within a fourteenth millionth part of the weight, in weighing small quantities; a balance formerly used by Dr. Priestley; and Professor Hennessy's standards derived from the earth's polar axis, as common to all terrestrial meridians.

Next comes fifthly, *the Measurement of Time*, which although of ancient conception has been reduced to mathematical precision only in modern times. This has taken place through the discovery by Galileo, of the pendulum, and its application by Huygens to time-pieces in the 17th century. The most interesting exhibits in this branch of measurement are, from an historical point of view, the Italian, German, and English clocks of the 17th century, the Timekeeper which was twice carried out by Captain Cook, first in 1776, and which, after passing through a number of hands, was brought back to this country in 1843, and an ancient striking clock, supposed to have been made in 1348; it has the verge escapement which is said to have been in use before the pendulum. The methods employed in modern clocks and watches for compensating for variation of the thermometer and barometer, are illustrated by numerous exhibits, notably the Astronomical Clock, with Sir George Airy's compensation, which will form the subject of a special demonstration by Messrs. Dent and Co.

The measurement of small increments of time has been rendered possible only in our own days by the introduction of the conical pendulum, and other apparatus of uniform rotation, which alone conveys to our minds the true conception of the continuity of time. Among the exhibits belonging to this class, must be mentioned Sir Charles Wheatstone's rotating mirror, moved by a constant falling weight, by which he made his early determination of the velocity of electricity through metallic conductors; the rotative cylindrical mirror, marked by successive electrical discharges, which was employed by Dr. Werner Siemens in 1846, to measure the velocity of projectiles, and has been lately applied by him for the measurement of the velocity of the electric current itself, and the Chronometric Governor, introduced by him in conjunction with myself, for regulating Chronographs, as also the velocity of steam engines under their varying loads; Foucault's Governor, and a considerable variety involving similar principles of action.

Another entity which presents itself for measurement is, sixthly, that of *Velocity*, or distance traversed in a unit of time, which may either be uniform or one influenced by a continuance of the cause of motion, resulting in acceleration, subject to laws and measurements applicable both in relation to celestial and terrestrial bodies. I may here mention the instruments latterly devised for measuring the acceleration of a cannon-ball before and after leaving the mouth of the gun, of which an early example has been placed within these galleries. Other measurers of velocity are to be found here, Ships' Logs, Current Meters, and Anemometers.

In combining the ideas of weight or pressure with space, we arrive at seventhly, the conception of work, the unit of which is the foot-pound or kilogrammetre, and which, when combined with time, leads us to the further conception of the performance of duty, the horse-power as defined by Watt. The machines for the measurement of work, here exhibited, are not numerous, but are interesting. Among these may be mentioned Professor Colladon's Dynamometrical Apparatus constructed in 1844; Richard's Patent Steam Engine Indicator, an improvement on Watt's, and Mr. G. A. Hirn's Flexion and Torsion Pandynamometers.

Eighth. The Measurement of *Electrical Units*—of electrical capacity of potential—and Resistance, forms a subject of vast research, and of practical importance, such as few men are capable of doing justice to. It may be questioned, indeed, whether Electrical Measurement belongs to the province of mechanical science, involving, as it does, problems in physical science of the highest order; but it may be contended on the other hand that at least one branch of Applied Science, that of Telegraphy, could not be carried on without its aid. I am happy to say that this branch of the general subject will be brought before you by my esteemed friend Sir William Thomson, than whom there is no one more eminently qualified to deal with it. I may, therefore, pass on to the next great branch of our general subject, the ninth: *Thermal Measurement.*—The principal instrument here employed is the thermometer, based in its construction, either upon the difference of expansion between two solids, or on the expansion of fluids such as mercury or alcohol—(the common thermometer) or upon gaseous expansion (the air thermometer); or again, it may be based upon certain changes of electrical resistance, which solids and liquids experience when subjected to various intensities of heat. With reference to these, the air thermometer represents most completely the molecular action of matter which is the equivalent of the expansibility. I shall not speak of the different scales that have been adopted by Réaumur, Celsuis and Fahrenheit, which are based upon no natural laws or zero points in nature, and which are therefore equally objectionable upon theoretical grounds. Would it not be possible to substitute for these a natural thermometric scale? One commencing from the absolute zero, of the possible existence of which we have many irrefutable proofs, although we may never be able to reach it by actual experiment. A scale commencing in numeration from this hypothetical point would possess the advantage of being in unison throughout with the physical effects due to the nominal degree, and would aid us in appreciating correctly the relative dynamical value of any two degrees of heat which could be named. Such a scale would also fall in with the readings of an Electrical Resistance Thermometer or Pyrometer, of which a specimen has been added to this collection by myself.

When temperature or intensity of heat is coupled with mass we obtain the conception of quantity of heat, and if this again is referred to a standard material, usually water, the unit weight of each being taken, we obtain what is known as specific heat. The standard to which measurements of quantity of heat are usually referred is the heat required to raise a pound of water one degree Fahrenheit, or the cubic centimetre of water one degree Centigrade.

The most interesting exhibits in this branch of measurement, are, from an historical point of view, the original spirit thermometer of the Florentine Academia del Cimento, and the photographs of old thermometers; the original Lavoisier Calorimeter for measuring the heat disengaged in combustion, Wedgwood's and Daniell's Pyrometers.

As illustrating modern improvement may be instanced a long brass-cased thermometer showing the variation in the readings, when the bulb and when the whole thermometer is immersed; a thermometer with flat bulb to improve sensitiveness; a thermo-electric alarum, for giving notice when a given temperature is reached; an instrument for measuring the temperature of fusion by means of electric contact invented by Prof. Himly; Dr. Andrews' apparatus for measuring the quantity of heat disengaged in combustion; Dr. Guthrie's diacalorimeter for measuring the conductivity of liquids for heat, and a thermometrictu be by Prof. Wartmann for determining the calorific capacities of different liquids by the process of cooling.

Finally, Joule has taught us how to measure the unit of heat dynamically, and the interesting apparatus employed by him from time to time in the various stages of the determination of this most important constant in applied mechanics, are to be found, rightly placed, not among thermometers, and other instruments placed in the physical sections, but among the instruments required in

the determination of three great natural standards—of length, time, and mass, and their combinations.

Another branch of the general subject is the *Measurement of Light*, which may be divided into two principal sections, that including the measurement of the wave-length of lights of different colours, and the angle of polarization, which belongs purely and entirely to physical science; and the measurement of the intensity of light by photometry, which, while involving also physical problems of the highest order, has an important bearing also upon applied science. The principal methods that have been hitherto employed in photometry are by the comparison of shadows, that of Rumford and Bouguer; by employing a screen of paper with a grease-spot, the lights to be compared being so adjusted that the spot does not differ in appearance from the rest of the paper, Bunsen's method; Elster's, by determining in combustion the amount of carbon contained in a given volume of a gas; and the one lately introduced by Prof. Adams and Dr. Werner Siemens, by measuring the variation in the electrical resistance of selenium, under varying intensities of light.

Before concluding, I wish to call your attention to two measuring instruments which do not fall within the range of any of the divisions before indicated. The first is an apparatus designed chiefly by my brother, Dr. Werner Siemens, by which a stream composed of alcohol and water, mixed in any proportion, is measured in such a manner that one train of counter wheels records the volume of the mixed liquid; whilst a second counter gives a true record of the amount of absolute alcohol contained in it. The principle upon which this measuring apparatus acts may be shortly described thus:—The volume of liquid is passed through a revolving drum, divided into three compartments by radial divisions, and not dissimilar in appearance to an ordinary wet gas-meter; the revolutions of this drum produce the record of the total volume of passing liquid. The liquid on its way to the measuring drum passes through a receiver containing a float of thin metal filled with proof spirit, which float is partially supported by means of a carefully-adjusted spring, and its position determines that of a lever, the angular position of which causes the alcohol counter to rotate more or less for every revolution of the measuring drum. Thus, if water only passes through the apparatus the lever in question stands at its lowest position, when the rotative motion of the drum will not be communicated to the alcohol counter, but in proportion as the lever ascends a greater proportion of the motion of the drum will be communicated to the alcohol counter, and this motion is rendered strictly proportionate to the alcohol contained in the liquid, allowance being made in the instrument for the change of volume due to chemical affinity between the two liquids. Several thousand instruments of this description are employed by the Russian Government in controlling the production of spirits in that empire, whereby a large staff of officials is saved, and a perfectly just and technically unobjectionable method is established for levying the excise dues.

Another instrument, not belonging to any of the classes enumerated, is one for measuring the depth of the sea without a sounding line, which has recently been designed by me, and described in a paper communicated to the Royal Society. Advantage is taken in the construction of this instrument, of certain variations in the total attraction of the earth, which must be attributable to a depth of water intervening between the instrument and the solid constituents of the earth. It can be proved mathematically that the total gravitation of the earth diminishes proportionately with the depth of water, and that if an instrument could be devised to indicate such minute changes in the total attraction upon a scale, the equal divisions on that scale would represent equal units of depth. (See NATURE, vol. xiii., p. 431.)

Gravitation is represented in this instrument by a column of mercury resting upon a corrugated diaphragm of thin steel plate, which in its turn is supported by the elastic force of carefully tempered springs representing a force independent of gravitation. Any change in the force of gravitation must affect the position of this diaphragm and the upper level of the mercury, which causes an air-bubble to travel in a convolute horizontal tube of glass placed upon a graduated scale, the divisions of which are made to signify fathoms of depth. Special arrangements were necessary in order to make this instrument *parathermal*, or independent of change of temperature, as also independent of atmospheric density, which need not be here described. Suffice it to say that the instrument, which has been placed on board the S. S. *Faraday* during several of her trips across the Atlantic, has given evidence of a remarkable accordance in its indications with measurements taken by means of Sir William Thomson's excellent pianoforte wire-sounding machine; and we confidently expect that it will prove a useful instrument for warning mariners of the approach of danger, and for determining their position on seas, the soundings of which are known.

Another variety of this instrument is the horizontal attraction meter, by which it will be possible to obtain continuous records of the diurnal changes in the attraction of the sun and moon as influencing the tides. This instrument belongs, however, rather to the domain of physics than to that of mechanical science.

These general remarks upon the subject of measurement may suffice to call your attention to its importance, several branches of which, those of *Linear*, *Cubical*, and *Electrical Measurement*, will now be dealt with.

The discussions which will follow these addresses will be carried on under circumstances such as have never before co-operated, namely, the presence of leading men of science of all civilised nations, who will take part in them, and the easy reference which can be had to the most comprehensive collection of models of scientific apparatus—both of modern and ancient—which has ever been brought together.

SCIENCE AT THE MANSION HOUSE

FOR the first time probably in the history of this country, science has been publicly acknowledged as a great force or power in the kingdom, on a level with literature and art. This, we think, is the legitimate conclusion to be drawn from the entertainment on Saturday by the Lord Mayor at the Mansion House of so many distinguished representatives of science, following hard as it did upon the opening of the loan collection by her Majesty the Queen. The company was numerous—there were about 300 present—as well as distinguished, and included several eminent foreign representatives of science, who have come over to the opening of the loan collection. The meeting was quite as successful as such meetings usually are, and the speeches on the whole much more sensible and appropriate. The following report of the speeches we take from the *Morning Post*:—

The Lord Mayor, in proposing the toast of the evening, "The Representatives of Science," spoke very happily. We were scarcely, he said, conscious of what we owed to science. If the inventor of the first small crane or lever for lifting water from a well were to come upon the scene now-a-days he would have some difficulty in persuading himself that it was the same world, and not some kind of paradise very far in advance of the world with which, in his day, that person was acquainted. Science was one of the mightiest of all the intellectual pursuits that man could follow. His Lordship said he had an intense admiration for the representatives of literature, but he could hardly express the feelings with which he regarded the men who laboured in the various phases of science. What did we owe to it? and what

were we coming to? To science we owed every easement we enjoyed in the work of our daily life. Science enabled us, in comparison with past generations, to live our lives over and over again. It enabled us to travel such mighty distances within so short a space of time as a few years ago would have been inconceivable; and, what with the aid of the electric telegraph, it placed us in almost immediate communication with nearly all parts of the world. Having referred to the vast saving of manual labour which had been effected through the aid of science by machinery and appliances of various kinds, his Lordship expressed his gratification at the presence of representatives of so many branches of science.

Dr. Hooker, who was the first to respond, remarked that the occasion might be regarded as marking an important epoch in the history of science. It had been his pleasure to attend the various exhibitions for the promotion of science and art which had been held in this country and abroad by our own and by other Governments since 1851, and not only to study their contents but also to inquire into their origin and connection, and what might be called their individuality. With respect to the exhibition which the present banquet might be said to commemorate, he could see many marks which distinguished it from those that had gone before it. It had been brought to its present remarkable state by the indomitable energy of a very few workers whom it might be invidious to particularise, though he could not forbear mentioning the name of Mr. Lockyer. Originating as it did almost spontaneously, it had received the support of the Government from the active interest that was taken in it by the Lord President and the Vice-President of the Council, and from the diplomatic action which resulted in getting foreign Governments to send their delegates to visit the exhibition and to take part in conferences on the occasion of its opening. It had derived no small support from the countenance which had been graciously bestowed upon it by the Queen. In continuation, Dr. Hooker said, look at the state of science now and what it was 300 years ago. It had advanced with such strides as had marked the progress of no other branch of intellectual pursuit. Compare, or rather contrast, the progress of science in modern times with that of literature and the fine arts. With regard to literature, as with regard to the fine arts in this country, more especially in the case of sculpture and architecture, we had to look back ages almost to find a starting-point in their general progress, and even in the case of the most modern of the fine arts—painting—we were referred back to the cradles of its birth in Italy, Spain, and the Low Countries. With regard to the Exhibition for the Advancement of Science, what was to be its future? Was it to be a matter of a few weeks or months, and then to pass away for ever? It was to be hoped not. It was the earnest desire of scientific men to form the nucleus of a great national museum of a permanent character for the benefit not only of scientific men but for the benefit of the public in general, and he felt sure that science would not look to the public in vain for aid in the endeavour to realise that important object. It was an object worthy of great and noble efforts, and he felt assured that such efforts would not be wanting on the part of the City of London.

After a few remarks from Sir John Hawkshaw, Sir George Airy, the Astronomer Royal, replied for that branch of the toast which he represented, and spoke of science under two heads, which, for want of better terms, he said he might describe as practical and contemplative science. Of the present state of practical science it was impossible to speak too highly. It was impossible for any one who had even a partial acquaintance with what was going on in our manufacturing districts especially, and in all those labours which were for the benefit of mankind, not to be struck with the enormous amount of ingenuity and enterprise which were brought to bear upon those industries with a view to material gain. Material gain was the aim of practical science. As for what he termed the contemplative branch of science, which embraced especially all those pursuits relating to the constitution of nature, the object in that case was not material gain or personal advantage, but the results at which it aimed were in their way not inferior to or less welcome than those of practical science.

Mr. Justice Grove in proposing "The Health of the Lord Mayor," humorously remarked that his lordship when inviting such a body of representatives of science to partake of his splendid hospitality, must have been actuated, not only by a lively sense of favours received, but also by a lively sense of favours to come. Mindful of what science had done for commerce and manufactures in the past, the first magistrate of the city of London had doubtless an eye at the same time to the advantages which manufactures and commerce would reap from the labours of science in the future. There was nothing in which the Lord Mayor could do himself more honour than in entertaining at his table the votaries of science, to whom, on the other hand, nothing could be more gratifying or encouraging than this mark of recognition and appreciation on his part of the value of their labours.

To the toast of "The Foreign Representatives of Science," Prof. Blaserna responded.

Altogether, we think, both the Lord Mayor and the representatives of science are to be congratulated on the success of this entertainment, which will no doubt form a precedent for future ones of a similar kind.

NOTES

COL. PREJEVALSKY is about to set out on a new exploring journey into Central Asia, which will probably last for about three years. His purpose is to explore especially the basin of the Lob-nor from Thian-shan to the Himalayas. Col. Prejevalsky proposes to visit this summer Eastern Thian-shan from Kulogra to Hama, and to pass the winter upon the Lob-nor and in the deserts which extend to the east of this lake, mainly to solve the question as to wild horses and camels. Next spring he will observe the migrations of birds on Lob-nor and proceed to Lhassa. He will then explore the upper course of the Brahamapootra and the northern slopes of the Himalayas, as also Eastern Thibet and Southern China, and if circumstances permit, he will return by Western Thibet and enter Russia by Kashgar. The programme of the expedition is as follows: 1. Geographical and ethnographical descriptions. 2. An itinerary sketch at sight. 3. Astronomical determinations of places. 4. Meteorological, psychometric, and hypsometric observations. 5. Observations of mammals and birds. 6. Botanical, zoological, and mineralogical collections. 7. Photographic sketches. The Russian Geographical Society has expressed its emphatic approval of the programme, and the Emperor has ordered 24,740 roubles to be devoted to the expedition from the treasury.

FROM Commander Cookson we hear that H.M.S. *Petrel* is bringing home two living specimens of the Giant Tortoise of the Galapagos Islands, from Albemarle Island. A large supply of food was provided, and if this does not fail, and at the same time if the cold in the region of Cape Horn has not proved too intense, we may hope to see the specimens alive, for the first time in this country, during next month.

FROM the *Rochester Democrat and Chronicle* (U.S.) we learn that a gentleman of Rochester, New York, who does not wish his name to be published, has, through Prof. Henry A. Ward of that city, given to the University of Virginia, a sum of 5,500*l.* to be expended in the formation of a fully appointed cabinet of the

natural sciences, including mineralogy, geology, and zoology The donor has also given a building, at the cost of more than 4,000*l*., for the collection to be built near Charlesville, four miles from Monticello Prof Ward, in making the collection, will visit the principal European cities

In the *Proceedings of the Royal Irish Academy*, p 427, Dr Robinson gives us a paper on the theory of the cup anemometer, and the determination of its constants The paper is an extremely valuable one, as indicating the line of research to be followed in prosecuting anemometrical experiments So far as we are aware, Dr Robinson is the first who has formed a just apprehension of the viscosity of the air in its bearings on such experiments, and adopted the necessary precautions in accordance therewith

At the meeting of the Edinburgh Botanical Society, held on the 11th inst, an interesting communication was read from the Rev D Landsborough, on experiments in growing several Australian plants and trees in Arran, in the Firth of Clyde, including among others the great Australian tree fern and other tree ferns, acacias, and gum trees The blue gum grew 11½ inches the first year 4 feet the second, and 6 feet the third The *Eucalyptus pendulosa* also grows well in sheltered situations along the west coast, and Mr Landsborough expects to see it generally introduced in a few years, and form a valuable addition to our evergreen shrubs

A correspondent writes with reference to the "Plaster cast of portion of antler of reindeer from La Madelaine, Dordogne France in the loan collection, the original of which is preserved in France The thicker end, the label states, is pierced with a hole "There are as many as four holes in some specimens Their use is unknown" Our correspondent states that these implements may have been used by former inhabitants of France in the same manner as a very similar tool usually made of deer horn is now in use or was very recently, by some tribes of the "Red men" of North America Where bows and arrows are in use, the arrows are made of a very hard and tough willow This willow may not always be quite straight, or is liable to get warped or crooked in the process of drying If so the bent or curved parts are straightened by the intended arrow being put through the hole in the horn, and a strong pressure applied in the proper direction to counteract the curve This has sometimes to be done over and over again before perfect straightness is obtained It may be asked why are three or four holes sometimes found in the same piece of horn? If the holes are of different sizes the reply is not difficult It is probable that the people who use these tools had wood of different thicknesses (say for arrows and spears) to manipulate, if so, holes of different sizes would be required It will, he thinks, be generally noticed that the edges of the holes are rounded, this would be done to prevent the otherwise sharp edge injuring the fibre of the wood. Near the specimen referred to, there is one in which one side of the hole has apparently been broken away by a violent strain, possibly applied in the manner and for the purpose above stated

The able director of the Royal Zoological Museum of Lisbon, José Vincente Barboza du Bocage, well known for his valuable researches on the natural history of the shores of Portugal, and especially on the Fauna of the Portuguese possessions in Africa, was unanimously elected a foreign member of the Linnean Society at their last meeting, May 4 Prof William Nylander, of Helsingfors, a cryptogamic botanist of deservedly high reputation, also had the same honorary distinction conferred on him

Parts xlvii and xlviii. of Mr. Dresser's "History of the Birds of Europe," completing the fourth annual volume of this important work, has just been issued with its usual punctuality Nearly 400 species of birds have now been figured and described, and as the total European avifauna is probably between 600 and 700 species, three more volumes will be required These will, almost certainly, be issued within three years from the present date, and we may therefore with great confidence anticipate the successful conclusion of a monograph, which, whether for the beauty of its illustrations, or for the fulness and accuracy of its information, will stand in the very first rank of ornithological literature

In Petermann's *Mittheilungen* for May is an article, accompanied by a map, showing the number, classification, distribution &c, of the institutions for higher instruction in Germany Following the continuation of the analysis of Prejevalsky's Mongolian travels is an interesting article on the recent travels of Dr Emil Holub in South Africa, mainly in the Limpopo and Zambesi regions and the region of the salt pans between Chutimi and Mamusa The information seems to be mainly obtained from the *Diamond News and Griqualand West Government Gazette* of Feb 23, 1875 Probably the most interesting article is a detailed account of Giles's expedition from Beltana in South Australia, to Perth in Western Australia, in May November, 1875 Giles's route was on an average four degrees to the south of Forrest's, which, again, was about the same distance south of that of Warburton Giles has the same barren tale to tell as his predecessor We believe he is to make a diagonal journey from north west to south east, though from this we can hardly expect many new results A valuable map accompanies the paper in the *Mittheilungen*, which is to be continued

The latest news received by the Russian Geographical Society from Dr Miclucho Maclay is dated from Cheribon (Java) in March last He announces that before leaving Batavia he sent to St Petersburg many zoological collections, and will bring his anthropological and ethnographical collections to Europe on his return, in 1877

A branch of the Russian Geographical Society will probably be shortly founded at Omsk, in Siberia

M de Mainof, Secretary of the Ethnographical Section of the Russian Geographical Society, has announced to the society that he is preparing a complete treatise on Russian ethnography It will appear in parts, each containing a description of a section of the people

M L Estourgies has been charged by the Belgian Government, in company with M Sylvain Jacquemin, civil engineer, to make a scientific journey through the Transvaal Republic

There is to be a Congress of Alpine Clubs at Pistoja and Florence on June 10 and 11 Several expeditions have been arranged

Mr J H Angus has made a gift to the Adelaide University, of a scholarship of 2,000*l* yearly, tenable for three years, to encourage the training of scientific men, especially civil engineers, with a view to their settlement in South Australia, the winner of the scholarships to spend six months of the term in visiting the great engineering works of Europe or America, towards which the donor gives 100*l* additional

Mails for the Polar ships *Alert* and *Discovery* will be made up for conveyance from Portsmouth on or about May 25, by the steam yacht *Pandora*, Capt Allen Young having kindly consented to convey letters for the officers and crews of the Polar ships to be deposited at the depots All letters should be sent through the post-office prepaid the inland rate of postage, and addressed "Arctic Yacht *Pandora*, Portsmouth." No letters

containing articles of value should be sent. No newspapers should be sent, as the Admiralty will send a sufficient supply.

THE University of Oxford is to confer upon Dr. Warren De la Rue the degree of M.A. by diploma.

THE ANNUAL Meeting of the Victoria Institute is postponed from the 22nd to the 29th of May.

LIEUT. CAMERON will, on Tuesday next, read to the Anthropological Society a paper on the Anthropology of Central Africa, in the theatre of the Royal School of Mines, Jermyn Street, at 8.30 P.M.

DOCENT THEEL, zoologist, a member of the Swedish Expedition of last year, to Novaya Zemlya, Docent Arnell, botanist, and Dr. Trybom, entomologist, have left Stockholm for Riga, whence they proceed overland to Siberia, where they will remain till autumn, making scientific observations and collections, and returning by the steamer *Ymer*, which Prof. Nordenskjöld has chartered for a voyage to the Yenisei.

M. JANSSEN, although he has not yet obtained possession of his regular observatory, has established large photographising telescopes at his residence at Montmartre. He found that during the cold period from the beginning of May up to the 10th, the sun had no spots at all. The photographs are about twenty centimetres in diameter.

C. M. STUART, of Harrow School, has been elected to the Natural Science Exhibition at St. John's College, Cambridge. A second exhibition was at the same time conferred on J. Nall, of Manchester Grammar School.

AT a recent meeting of the French Academy, M. Lecoq de Boisbaudran communicated some further facts regarding the new metal gallium. The specimen he had formerly presented owed its solidity to the presence of a small quantity of foreign bodies. Pure gallium, of which he had now prepared nearly ten centigrammes, melts at about 29°·5 C.; hence it liquefies when it is seized between the fingers. It is very easily held in superfusion, which explains how a globule has been kept liquid for weeks in temperatures descending occasionally almost to zero. Electrolysed gallium from ammoniacal solution is identical with that obtained from potassic solution. Once solidified, the metal is hard and resistant, even at a few degrees under its melting point; but it can be cut, and has a certain malleability. Melted gallium adheres easily to glass, on which it forms a beautiful mirror, whiter than that produced by mercury. Heated to a bright red in presence of air, gallium oxidises but very superficially, and does not volatilise; it is not sensibly attacked in the cold state by nitric acid, but in heat the solution operates with liberation of nitrous vapours. The density of the metal (determined approximately from a specimen weighing sixty-four milligrammes) is 4·7 at 15°, and relatively to water at 15°. The mean of the densities of aluminium and of indium is 4·8 at zero. Thus the density confirms theoretical prevision, while the extreme fusibility is a fact completely unexpected.

THE Marine tanks of the Royal Aquarium, Westminster, are being rapidly filled with water brought from Brighton by Messrs. Hudson, who supplied the Crystal Palace. For some time past many of the fresh-water tanks have been stocked, but the first marine fish has but quite recently arrived. It is a somewhat rare one in captivity—the *Motella tricerata* (Yarrell), commonly called the spotted leopard fish. It is placed in a central tank, so that the peculiarity of the "fin" in the neck can be well seen. Couch, in his "History of Fishes," refers to this fin as being always in rapid action, but with this particular specimen it is often at rest. He points out that while its intimate structure shows that it is destitute of any power of propulsion or of regulating motion, it is well furnished with nerves which render it acutely sensible to impression. The functions of the fin have, so far as we know, not been determined.

MR. WALPOLE, on Tuesday, moved for leave to introduce "A Bill for making further provision respecting the University of Cambridge and the Colleges therein." Following the recommendations of the Duke of Devonshire and the Oxford and Cambridge University Commissions, he indicated the nature of the changes desired as follows:—The extension of the professoriat, and a complete organisation of the system of inter-collegiate lectures and classes, for which provision would have to be made over and above that which had already been made, for museums, libraries, and the other apparatus which might be necessary for the prosecution of scientific investigation. The following are the names of the seven Commissioners it is proposed to appoint:—The Bishop of Worcester, Lord Rayleigh, the Lord Chief Justice, the Right Hon. E. P. Bouverie, Prof. Stokes, Rev. Prof. Lightfoot, and Mr. G. W. Hemmings. Mr. Cross said the Bill might be regarded for all practical purposes as a Government measure.

THE animals deposited in the Gardens of the Zoological Society by H.R.H. the Prince of Wales, include, among others, two Musk Deer (*Moschus moschiferus*); two Thar Goats (*Capra jemlaica*); four Indian Elephants (*Elephas indicus*), aged about 7, 6, 1½ and 1½ years; five Tigers, (*Felis tigris*); a Cheetah (*F. jubata*); a Viverrine Cat (*F. viverrina*); five Leopards (*F. pardus*); an Indian Civet Cat (*Viverricula indica*); two Dwarf Zebus (*Bos indicus*); seven Indian Antelopes (*Antilope cervicapra*); three Axis Deer (*Cervus axis*); three Ostriches (*Struthio camelus*); several pairs of Impeyan Pheasants (*Lophophorus impeyanus*); Cheer Pheasants (*Phasianus wallichii*); Horned Tragopans (*Ceriornis satyra*); Chukar Partridges (*Caccabis chukar*). Besides the Prince's specimens, the following are the most important additions of the week:—Two Secretary Vultures (*Serpentarius reptilivorus*), presented by Mr. M. G. Angel; an Egyptian Cobra (*Naja haje*), presented by the Rev. G. H. R. Fisk; and a Maholi Galago (*Galago maholi*), presented by Dr. R. A. Zeederberg, all from S. Africa.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, May 4.—On the Modification of the Excitability of Motor Nerves produced by Injury, by G. J. Romanes, M.A., F.L.S.

It has long been known that when a nerve is cut, or otherwise injured, its excitability at or near the seat of injury undergoes a marked increase. No one, however, has attempted to determine the relative degree of this increase towards make and towards break of the current respectively. The author found that when the nerve-section rested on the *kathode*, the *increase* of excitability was manifested towards *make*, and scarcely at all towards break; while, conversely, when the section rested on the *anode*, such *increase* was manifested towards *break*, and scarcely at all towards make. These facts are of considerable interest in relation to the theory of electrotonus. The *degree* of the latter increase, however, is out of all proportion greater than that of the former; for while the ratio of excitability before and after cutting was represented by the numbers 36 : 46 in the case of the kathodic make, such ratio was represented by 2 : 32 in the case of the anodic break. Mr. Romanes explains this disproportion by the consideration, that as the sensitiveness to the kathodic make is so much greater than is that to the anodic break *before nerve-section*, after the general sensitiveness of the nerve has been increased by section, the increase has not so much room to assert itself in the former as it has in the latter case, before it reaches zero of the stimulating current's intensity. Thus the figures 2 : 32 :: 36 : 46, though not expressing any *numerical* proportion, may yet express a *real* proportion, if the zero of the current's intensity be represented say by 50 in the above scale of nervous excitability, and if it be granted that the value as a stimulus of any given increment of current is determined by the proportion which such increment bears to the intensity of current that is required to produce adequate stimulation. This explanation is confirmed by a method of graduating the galvanic stimulus other than that of graduating the intensity of the current, viz., by

graduating its *duration*. In this way it was found that, in respect of voltaic stimuli of very short duration, the sensitiveness to the kathodic make is much more increased by cutting than is that to the anodic break.

Mr. Romanes further observed that when a frog's gastrocnemius is subjected to a weak galvanic current, a part or parts of it will sometimes pulsate in a strictly rhythmical manner. This was proved to be a nervous effect by observing that it ceased when the attached sciatic was thrown into anelectrotonus.

With minimal stimulation of curarised muscle, the author found that considerably more effect is produced by first laying on the anode and then the kathode, than is produced if this order is inverted. This fact is just the converse of what Hitzig found to be true of cerebral stimulation, and as such it may be taken as confirmatory of his views concerning the reversed relations that subsist between central and peripheral voltaic excitation.

May 11.—"On some Thallophytes parasitic within recent Madreporaria." By P. M. Duncan, M.B. F.R.S., President of the Geological Society.

"Condensation of Vapour of Mercury on Selenium in the Sprengel Vacuum." By R. J. Moss, F.C.S., Chemical Laboratory, Royal Dublin Society. Communicated by G. Johnstone Stoney, F.R.S.

Royal Microscopical Society, May 3.—Mr. H. C. Sorby, F.R.S., president, in the chair.—Mr. Chas. Brooke, F.R.S., proposed a special vote of thanks to the president for the conversazione given by him on the 21st inst.—A paper was read by Mr. Blake on the occurrence of what appeared to be Foraminifera in the coralline oolite, and specimens in illustration were exhibited under microscopes in the room.—Mr. J. Glaisher communicated a paper by Dr. Gayer, describing the apparatus employed and the process adopted by him in India for the purpose of taking photo-micrographs with high powers.—A paper by Dr. J. J. Woodward on the markings of the body-scale of the English gnat and the American mosquito was read by the Secretary.—Some notes upon the same subject by Dr Anthony were also communicated.—A short paper by Mr. Stodder on the identity of *Frustulia saxonica*, *Navicula rhomboides*, and *N. crassinervis* was read by the Secretary.—Mr. Chas. Stewart called attention to a curious living organism exhibited by Mr. Badcock, and which the Fellows present were requested to examine with a view to its identification.

Victoria (Philosophical) Institute, May 8.—After the election of new members, of whom fifty were announced as having been admitted during the past four months, it was stated that Prof. Birks would deliver the Annual Address for 1876.—A paper on the metaphysics of Scripture was then read by Prof. Challis, F.R.S.

BERLIN

German Chemical Society, March 27.—A. W. Hofmann, president, in the chair.—A. Fluckiger has proved the presence of *carvacrol* in the oils of *mentha viridis* and of *anethum graveolens* by producing its characteristic combination with sulphuretted hydrogen.—O. Fischer described nitroso-acetanilide, $NC_6H_5 . C_2H_3O . NO$, an unstable compound from which acetaniline is easily reproduced.—J. Dummer, by the action of amidophenol, $C_6H_4OHNH_2$, on sulphuret of carbon, has obtained an oxysulphocyanide of phenyl, C_7H_5NSO.—W. Smith has observed, that by passing through a red-hot tube naphthaline-vapour together with terchloride of antimony or tetrachloride of tin, a good yield of dinaphthyle is formed—

$$6C_{10}H_8 + 2SbCl_3 = Sb_2 + 6HCl + 3C_{20}H_{14}.$$

W. Thoerner has studied the action of hydrogen and of chlorine on tolylphenyl ketone. The latter gives rise to three crystallised substitution compounds:—

$$C_6H_5 . CO . C_6H_4 . CH_2Cl, \quad C_6H_5 . CO . C_6H_4 . CHCl_2,$$
and
$$C_6H_5 . CO . C_6H_4CCl_3.$$

The latter with water yields the acid $C_6H_5 . CO . C_6H_4COOH$. With zinc and hydrochloric acid the ketone yields a pinacoline, $\begin{matrix} C_6H_5 \\ C_6H_5 \end{matrix}\!\!>C<\!\!\begin{matrix} C_6H_4CH_3 \\ CO . C_6H_4 . CH_3 \end{matrix}$, as well as an isomeride.—H. Limpricht described a number of substitution-compounds of meta-amido-benzosulphuric acid with bromine.—C. Councler has obtained borate of allyl, $Bo(OC_3H_5)_3$, a liquid boiling at 170°, by the action of boric anhydride on allylic alcohol.—Lothar Meyer, after decomposing sulphate of copper by metallic zinc, found in solution nothing but neutral sulphate of zinc, while metallic copper and basic sulphate of zinc were deposited on the metal. Evolution of hydrogen gas takes place during this process.

April 10.—H. Limpricht described new derivatives of sulphobenzolic acid.—H. W. Vogel reported on the spectroscopic reactions of blood.—Robert Schiff described the action of isosulphocyanide of phenyl with aldehyde-ammonia. The body expected $C = S—NHC_6H_5—NH . \underset{\displaystyle CH_3}{\overset{|}{CH}} . OH$, or $C_{11}H_{19}N_3O_2S$ loses water and ammonia, and yields a well crystallised substance, $C_{22}H_{31}N_5O_2S_2$, thus:—

$$2C_{11}H_{19}N_3O_2S—2H_2O—NH_3 = C_{22}H_{31}N_5O_2S_2.$$

The new body with acetic anhydride yields a phenylated and acetylated sulpho-urea: $C = S—NH . C_6H_5—NH . C_2H_3O$.—G. Schultz has treated isodinitrodiphenyl with tin and hydrochloric acid, thus transforming it into an isomeride of benzidine, called by the author diphenyline, $C_{12}H_8(NH_2)_2$, crystallising in colourless scales, and fusing at 53°.—W. Staedel and L. Rugheimer have studied the action of alcoholic ammonia on chloro-acetyl-benzol $C_6H_5—CO—CH_2Cl$. The results are two bodies. One insoluble in ether, but soluble in boiling alcohol, from which it crystallises in silky needles, fusing at 194°, proved to be isomeric with indol, having the formula $C_6H_5—C—CH_2$.
$$\diagdown\!\!\diagup$$
$$N$$
—The other substance soluble in ether appears to correspond to the formula $C_6H_5—CO—CH_2NH_2$.—E. Demole, studying the action of bromine on clorhydrine of glycol, has found the following products of reaction: bromide of ethylene, bromochloride of ethylene, bromhydrine of glycol and bromo-acetic ether.—F. Beilstein and A. Kurbatoff have prepared two tetrachlorobenzols in which the four atoms of chlorine are situated at 1 . 2 . 3 . 5 and 2 . 3 . 5 . 6 respectively; by starting from corresponding trichloranilines. The latter when oxydised yields chloranil, from which the authors conclude that in chinone the two atoms of oxygen occupy the positions 1 : 4.—E. Ullrich and H. von Perger described the differences between iso-anthraflavinic and anthroxanthinic acids.—F. Kessler described spectral apparatus for lecture purposes, the novelty of which consists in retransmitting the spectrum through the prism that engendered it, so as to obtain a dispersion of double magnitude.—II. Tollens described a shortened method of obtaining levulinic acid, $C_5H_8O_3$, from fruit sugar.—V. Meyer and F. Forster have repeated M. Emmemann's experience of decomposing normal propylamine with nitrous acid, and they arrive at the result that not only isopropylic alcohol but also normal propylic alcohol and propylene are thus engendered. The latter, combining with water, yields the isopropylic alcohol, the formation of which was hitherto unexplained.—O. Wallach and Th. Heymer have succeeded in combining directly chloral and trichlorolactic acid, thus forming chloralid, and proving that chloralid is the ether of trichlorethylidene with trichlorolactic acid. Lactic acid also combines with chloral.—A. Michaelis and E. Benzinger have reduced nitrophosphenylic acid to *amidophosphenylic* acid,

$$C_6H_4(NH_2) . PO(OH)_2,$$

white brilliant needles soluble in water. With soda-lime they yield aniline and phosphates. Nitrous acid transforms it into nitrate of diazophosphenylic acid: $PO_3H_2 . C_6H_4N = N . NO_3$. Phosphenylic acid and soda-lime yields benzol, while nitrophosphenylic acid and soda lime yields nitro-benzol. The same chemists have produced phosphenyl-bromide, $C_6H_5PBr_2$, a colourless liquid, by passing hydrobromic acid gas into the corresponding chloride. With bromine it forms two solids of the formula $C_6H_5PBr_4$ and $C_6H_5PB_{16}$ respectively.—H. Lecco has obtained from sodium-nitromethane, CH_2NaNO_2, an anhydride, $C_2H_3N_2O_3$.—W. Michler, from an acid lately described dimethylamidobenzoic acid, $C_6H_4 . N(CH_3)_2 . COOH$, has obtained a basic ketone,

$$C_6H_4 . N(CH_3)_2—CO—C_6H_4 . N(CH_3)_2.$$

A third rest, $C_6H_4N(CH_3)_2$ — can replace an atom of hydrogen in this ketone, thus producing a complicated non-basic ketone.—H. Zincke has obtained, by the action of H on β benzoyl-benzoic acid, an anhydride, $\begin{matrix} O — CO \\ | \quad\quad | \\ C_6H_5CH—C_6H_4 \end{matrix}$; and from it, by chloride of phosphorus, anthrachinone.—C. Liebermann and H. Palm described β bromonaphthaline, $C_{10}H_7Br$, obtained from β naph-

thylamine by passing through the corresponding diazo compound and naphthol – A Frank showed zeolith-like crystallisations in slowly-cooled glass The same chemist showed wrought iron transformed into silicium-iron by immersion in molten glass – C Bucking has transformed anisic aldehyde, $C_6H_4\begin{smallmatrix}OCH_3\\COH\end{smallmatrix}$ into paraoxybenzoic aldehyde, $C_6H_5\begin{smallmatrix}OH\\COH\end{smallmatrix}$, fusing at 111°

April 24 – N Gerber described an apparatus for closing the fat contained in milk —P J Anster has transformed solid dibromobenzoles into three isomeric dinitro dibromobenzoles, one of which he transformed into nitro dibromo aniline – R Lbert and V Marz described two isomeric disulphonaphthalic acids, $C_{10}H_6(SO_3H)_2$, formed simultaneously and separated by the unequal solubility of their chlorides in benzol With cyanide of potassium two bicyanides and the corresponding dinaphthoic acids were obtained, while fusion with potash transforms one of the sulpho-compounds into $C_{10}H_6(SO_3H)OH$, which with water yields β naphthol, while the other sulpho compound yields dioxy naphthaline with a melting point 186° – I Woreden discussed the constitution formula of naphthaline —I Priwoznik finds the crystals formed in Leclanche's battery to correspond to the formula $ZnCl_2(NH_3)_2$ – H Vogel defended the spectroscopic analysis of blood, sustaining that the spectroscopic reaction of indigo cannot be confounded with that of blood – A Oppenheim and H I mmerling have continued their researches on the oxidation of oxyuvitic acid Nitric acid yields hydro oxybenzoic acid, while a mixture of sulphuric with fuming nitric acid produces trinitrocresol apparently identical with that obtained by Liebermann from nitro coccinic acid —P Gri s has formed combinations of phenol with one molecule and with two molecules of diazobenzol

THURSDAY, MAY 25, 1876

LORD CARNARVON'S VIVISECTION BILL

THE Report of the Royal Commission appointed to consider the question of Vivisection has led to the introduction of a bill into Parliament, the clauses of which restrict the practice of experiments upon living animals to a very great extent. According to the act—

(1) Experiments must be performed with a view only to the advancement, by new discovery, of knowledge which will be useful for saving or prolonging human life, or alleviating human suffering.

(2) In a registered place.

(3) By a person holding a licence from one of her Majesty's principal Secretaries of State.

(4) The animal must, during the whole experiment, be under the complete influence of some anæsthetic, (not urari; and,

(5) Must be killed before it recovers from the influence of the anæsthetic.

(6) The experiment shall not be performed for demonstrational purposes; nor,

(7) For the purpose of attaining manual skill.

It is but natural to suppose that concomitantly with the rapid advances which have, within the last century or so, been made in our knowledge of scientific method, similar progress has occurred in the theory of legislation. And yet our leading politicians, in introducing the above quoted Bill, are bold enough to advance, as a motive for the legal machinery they are endeavouring to enforce, the idea that there is any real substantiality in the notion that the lengthening of human life and the alleviation of human suffering can form any direct stimulation to physiological work. In so doing they show how little they are capable of appreciating the spirit of the higher philosopher, whose thoughts and temptations to investigate, however much they may be disguised by secondary motives, are but the involuntary secretion, as it may be termed, of his individual brain. They do not even seem to know that one of the most fundamental of the data of scientific method precludes the possibility of preconceived ideas of any kind forming part of a correctly stated problem.

Next with reference to the licence which must, according to the Bill, be held by all who desire to practice vivisection, we cannot help feeling that any legislation which at all interferes with higher mental work is cumbersome in the extreme; for it appears to us to be quite unjustifiable to trammel in the least, the genuine and honourable exercise of original power, whatever way it tends to show itself. There can be no doubt that the genuine student of biology, in as far as he is a pure student, should be in no way restricted in his researches. The Duke of Somerset's objection also deserves special notice, for "important discoveries are often made by comparatively unknown men, rather than by the most prominent physicians and surgeons, and yet such students were to be prevented from prosecuting their researches."

With regard to educational physiology, quite a different influence is at work. We are among those who think that for the purpose of demonstrating physiological facts to students, vivisectional experiments are, notwithstanding the opinion of Sir James Paget and others to the contrary, not absolutely necessary. One of the physiologists examined before the Commission brought forward the case of the teaching of surgery in our medical schools, in which science the opportunities for obtaining independent practical skill on the living body are *nil;* and yet we cannot believe that many serious mistakes occur from the want of it.

Such being the case, the supervision of public institutions where physiology is taught is quite in accordance with our views, as are the restrictions with reference to the employment of anæsthetics, and the destruction of the subjects of experiment before they have recovered consciousness.

As to the exemption of Cats and Dogs, we never heard anything more ludicrous, and we are glad that Lord Winmarleigh—as a member of the Royal Commission his opinion is weighty—objected to the restriction as unnecessary. It may be true, as Lord Carnarvon remarked in the House last Monday night, that the employment of these animals has slightly encouraged theft in their direction; but that this should be, by sober men, accepted as a reason for taxing physiologists to purchase more expensive animals, when a few more stringent sentences in the police courts would remove the evil, seems feeble in the extreme.

Looking at the Bill from a general point of view, its great defect is, in our estimation, its separate existence. The genuine spirit which actuates our nation, if we are not mistaken, is one which looks with disgust at the infliction of pain when unattended with the highest advantages. That this is not the case in some foreign countries we know, and can more fully realise since Dr. Klein has given his evidence before the Royal Commission. No doubt, as Lord Carnarvon remarked, "students are more and more in the habit of frequenting foreign Schools and returning to this country with the traditions and modes of these Schools." Would not a clause or so attached to the previously existing Cruelty to Animals' Act, however, cover all the requirements of the case by enabling an inspector, or a private individual, to prosecute any one performing a vivisection for simple demonstration purposes, or if he publishes results which show that due precaution has not been taken to reduce pain to a minimum in the animal operated on?

WILSON'S "PREHISTORIC MAN"

Prehistoric Man: Researches into the Origin of Civilisation in the Old and the New World. By Daniel Wilson, LL.D. Third Edition. (Macmillan and Co., 1876.)

DR. DANIEL WILSON claims the merit of having introduced the useful term *prehistoric*, first employed (he says) in 1851, in his "Prehistoric Annals of Scotland." There its meaning was limited to races preceding the oldest historical nations of Northern Europe. But in the first edition of his "Prehistoric Man," published in 1862, it had become a general term for tribes ancient or modern in chronology, as to whom

written history fails to afford information, and who are only known through archæology. The adoption of the word by Sir John Lubbock in the title of his "Prehistoric Times," published in 1865, and its incorporation into the name of the "Congress of Prehistoric Archæology," which held its first meeting at Neuchâtel in 1866, brought it into general currency.

The present third edition of Dr. Wilson's "Prehistoric Man" contains the principal dissertations of the original work. These are especially the account of the earthworks of the mound-builders of Western America, of the native-copper mines worked by the indigenes in the Lake Superior district, the details of stone and shell implements in America, and studies of American craniology The book has been now expanded so as to bring the new European evidence into connection with the American investigations, and in the course of correcting various rash statements made in the previous editions have been pruned away. It is of course not necessary to go over the contents as though the work were new, but the following are among the points calling for remark :—

Living at Toronto as Professor of History at the local University, and having had special opportunities of studying the indigenes of North America and their antiquities, Dr. Wilson sees the problems of general ethnology from a peculiar point of view, which is often an advantageous one. For instance, as an archæologist living within reach of the above-mentioned native copper workings of Lake Superior, he was naturally led to give due attention to the interesting intermediate stage here represented between the Stone Age proper and the Metal Age proper. The tribes of the district had got so far as to discover that the copper they found in blocks was a malleable stone of great value for making hatchets and other tools of, but they had not arrived at the next stages, those of learning to smelt copper from the ore, and to alloy it with tin. Such an intermediate stage may possibly have at some time existed also in the Old World (vol. i., p. 230). Dr. Wilson's remarks are interesting both on the use of native copper among the northern tribes of the continent, and on the manufacture of bronze in Mexico and Peru. But the author's American surroundings perhaps incline him to ascribe too readily to the native tribes an absolute independence in the development of their civilisation, uninfluenced during historic centuries (as he says) by any reflex of the civilisation of the Ancient World. We do not think that he ought to have assumed (vol. i. p. 224) that the art of bronze-making was developed in the native-born civilisation of Mexico and Peru. He seems to recognise (vol. ii. p. 60) Humboldt's argument, that the Mexican astronomical calendar came from Asia, and if so, why should not the art of bronze-making have come thence too, and at no very ancient date? Dr. Wilson himself points out the likeness between the mirrors of polished bronze found in the royal tombs of Peru and those now in use in Japan (vol. i. p. 244).

There are two assertions often made as to the inhabitants of the part of America with which Dr. Wilson is well acquainted. One is that the skull and face of the English race in the United States are becoming assimilated to the type of the North American Indians. On this Dr. Wilson's remark is simply negative: "I can scarcely imagine anyone who has had abundant opportunities of familiarising himself with the features of the Indian and the New Englander, tracing any approximation in the one to the other" (vol. ii. p. 329). The other assertion touches the intellectual powers of the Negro as compared with the white race. For instance, Sir Charles Lyell was told in Boston (as many other Englishmen have been) as a reason for the coloured children being taught separately from the whites, that although up to the age of fourteen the Negro children advanced in education as fast as the white children, after that point it became difficult to carry them on further. Dr. Wilson regards this statement as a mere excuse, intended to justify a separation really made through caste-prejudices (vol. ii. p. 325). Dr. Wilson's testimony is of consequence on these two points, which rest on so considerable authority, that they ought without delay to be settled one way or the other. We can only hope he will find time to go more fully into them, considering their importance as throwing light on climatic modification of race on the one hand, and intellectual difference between races on the other.

Dr. Wilson is evidently more critical as an ethnologist and antiquary than as a comparative philologist. It is a pity that among the new matter inserted in this edition, he should have put in a passage which may lead uninstructed readers to believe that a connection has been really made out between the Guarani of Brazil and the Agaw of the Nile region, or between the Akkadian of Babylonia and any American language (vol. ii. p. 346). Dr. Wilson mentions certain theories propounded by Mr. Hyde Clarke, but he does not even produce the evidence on which he relies. On the contrary, it may be said with some confidence, that as yet no philologist has proved any prehistoric connection whatever between any language of America and any language of the Old World, except of course, near the shores of Behring's Straits.

In fairness to Dr. Wilson, however, the value of other of his linguistic contributions must be acknowledged ; for instance, his list of imitative names of animals in Algonquin dialects, and his remarks on the Chinook jargon, and the *Pigeon*-English (*i.e.* *Business*-English) of the Chinese ports. The specimen of the latter (vol. ii. p. 333) is the introduction of a new English customer to a Chinese merchant :—"Mi chinchin you, this one velly good flin belong mi ; mi wantchie you do plopel pigeon along he all same fashion along mi," &c. On the whole Dr. Wilson is to be congratulated on the reappearance and revision of his work.

EDWARD B. TYLOR

THE ARALO-CASPIAN REGION

The Shores of Lake Aral. By Herbert Wood, Major R.E., F.R.G.S., &c. (London : Smith, Elder and Co., 1876.)

FROM the earliest times down to the present day there has always been a certain amount of mystery and uncertainty hanging around the Aralo-Caspian region. Major Wood in the work before us shows that the physical history of this ever-changing region is largely sufficient to account for this mysterious halo. Major Wood had an unusual opportunity for exploring Lake

Aral and the regions around it in 1874, having been allowed to accompany an expedition sent out under the auspices of the Russian Geographical Society to examine the Amúdarya. The results of this visit, as contained in the masterly work under notice, show that he took excellent advantage of so favourable an opportunity. Some of the most important of these results as regards the past and present physical condition of the Aralo-Caspian region were described by Major Wood in three papers which appeared in NATURE, vol. xi. p. 220, and vol. xii. pp. 51 and 313. To these papers we would refer those who want to get a succinct idea of some of the important conclusions which Major Wood has reached; but all who take an interest in physical geography generally, and this region in particular, we would advise to procure the work under notice.

The two main points discussed by Major Wood are the past and present condition of the Amúdarya or Oxus, and the existence at one time of a great Asiatic fresh-water Mediterranean Sea, of which the Black Sea, the Caspian, and Lake Aral are only remnants, and having communication by the region to the north of the last-mentioned lake with the Arctic Ocean. How small a change in the present conditions of the Black Sea would serve to give rise to such a great inland sea as Major Wood, on good grounds, supposes once to have spread its waters over a wide extent of Asia and Europe, may be seen from the following extract:—

"Supposing the outlet of the Bosphorus to be closed to the height of two hundred and twenty feet above sea-level, the superfluous waters of the Black Sea basin, which now flow off to the Mediterranean, would rise in level and encroach on the south Russian steppes and the lower Danube plains, though the coasts of Asia Minor, which form the southern boundary, would be but little changed on account of their steepness. On attaining a height of about twenty-three feet above sea-level[1] the waters would escape by the line of the Manytsch into the basin of the Caspian, and, after having filled it up also, would flood the country intervening between it and Lake Aral. In their ascent to this basin the waters would chiefly pass by the Emba steppes from the north-east of the Caspian basin, and from Balkhân Bay on the south-east, up the country crossed by the Uzboy channel of the old Oxus; for between the two seas lies the elevated plateau of Ust-Urt. This high ground has several detached portions near the Caspian shore, while the remainder of its surface is covered with numerous bowl-shaped depressions. These would, in all probability, have received the rising waters by ravines which enter the body of Ust-Urt from the low steppes upon its north and upon its south, and the aspect of the plateau would thus have been changed into that of the lake and marsh sprinkled highland whose traces remain to-day.

"In this imaginary reconstruction of the Asiatic Mediterranean, the moment the rising waters reached a point at about two hundred and ten feet above the sea, and which is situated at the head of the now dry gulf Abougir, they would have entered into and filled up the basin of Lake Aral."

Many indications exist at the present day pointing to the great probability of the existence, at some perhaps not very remote period, of such an inland sea. The fauna of the basins of the Black, the Caspian, and the Aral Seas are nearly identical; a glance at the fine map which accompanies the volume shows that the region to the north of the Aral is covered with lakelets, and evidence exists that in historical times the Aral was joined to the north part of the Caspian. The amount of evidence, historical and physical, produced by Major Wood in support of the ideas developed in his work, is very great, and we think in the main convincing.

The author devotes a number of chapters to the Amúdarya, the lower course of which he has explored with the greatest minuteness; indeed he seems familiar with every mile of it. He gives a clear and detailed account of the lower arms of the Amú—which are not at all of the nature of a delta by which it discharges itself into Lake Aral. No dependence can be placed on the permanence of these outlets, nor indeed it would seem upon that of any part of the Amú for the last 400 miles of its course. It is known that at one time it flowed into the Caspian, and Major Wood's work and map show how this could easily have been, and could easily be again brought about at the present day. From Tchardjui an old bed is seen to strike westwards to the Balkhan Bay of the Caspian, and from this branch again Major Wood adduces evidence to prove that, periodically at least, another must have struck south-westwards into the Attrek, which has been so much in the front recently. The Amú, indeed, throughout historical and no doubt prehistorical times, has been an ever-changing river, in its lower course at any rate; its frequent and perplexing changes being caused partly by the physical conditions which regulate its flow, and partly by the interference of man; for at the present as in past times the river is tapped at several places for the purpose of irrigating the desert regions which lie to the west. The river divides at Khodjeili into three main branches, which carry its water to Lake Aral; but these seem to be ever shifting, and the region embraced between them, inhabited by the poor Karakalpaks, seems to be mostly a swamp.

Major Wood also devotes some space to an account of the Syrdarya or Jaxartes, which at one time discharged a considerable proportion of its waters by the Jany Darya into the Amú, and thus probably ultimately into the Caspian. Major Wood traversed the district between the lower Amú and Fort Perofisky, the Kizzel Koom desert, and came across distinct traces of a former channel. But altogether the amount of evidence, historical and physical, which he brings forward to show the changes which have taken place in the region under consideration is almost bewildering. Greek, Arabic, Russian, and Chinese writers of all ages are quoted; indeed Major Wood seems to have collected every important scrap of writing that bears on the region he is investigating. This historical evidence, combined with the physical conditions of the region with which he has made himself thoroughly familiar, enable him to make out a strong case on behalf of all the points he desires to establish. The work must always be regarded as a standard reference-book on the hydrography of the Aralo-Caspian region. But it is something more; notwithstanding that it endeavours to solve some very hard questions, it is never dry, never uninteresting. It contains a record of a pleasant and profitable journey from Samara on the Volga to the Russian ports on the Syr, a

[1] This is the height of the surface of the lake, which exists in the bed of the Western Manytsch, at its higher extremity, though the level of the banks, at the bifurcation of the Eastern and Western Manytsch channels, is more. M. Hommaire de Hell stated this height to be nearly ninety feet above the sea, which is not very incorrect, though perhaps slightly in excess of reality.

cruise down the Sea of Aral, and up the Amú, and, as we have said, a journey across the dreary desert of Kizzel Koom. Major Wood conveys, we think, a clearer and more vivid idea of the region indicated, its aspects, and its inhabitants, their characteristics and habits, than any other author we know. The maps which accompany the volume are a great assistance. We may note that they give the present level of the Caspian as 85 feet below that of the ocean, Lake Aral being 158 feet above sea-level. This, we presume, may be taken as authoritative for the present, and it ought to be noted, as the statements on the point in various authorities differ in a most remarkable way.

Major Wood naturally speaks of the conduct of Russia in Asia with warm approval, and indicates several beneficial results which have followed her recent conquests. He believes that of all European powers she, partly from the simplicity of her Government, and partly on account of her ethnic affinities, is best suited to wean the wandering hordes of Central Asia to a settled and civilised life. We strongly recommend Major Wood's work as one of substantial value and great interest. But why has a work of such importance and so full of details, been allowed to go forth without an index. We hope this omission will be remedied at the first opportunity.

OUR BOOK SHELF

La Théorie des Plantes Carnivores et Irritables. Par Edouard Morren. (Bruxelles: F. Hayez, 1876.)

In this pamphlet, a report of an address given at the annual public meeting of the scientific section of the Royal Academy of Belgium, on Dec. 16, 1875, Prof. Morren gives an admirable *résumé* of the present state of our knowledge on these two branches of vegetable physiology. As regards the now well-known phenomena of carnivorous plants, he gives the most essential points of the observations of Darwin, Hooker, Lawson Tait, Reess and Will, the author himself, and others: and, in contrast to his relative, M. Charles Morren, he gives his full adhesion to the view that nitrogenous substances are actually digested by the leaves of *Drosera*, *Pinguicula*, and *Nepenthes*. He points out, indeed, that the theory is not a new one, having been promulgated by Burnett in 1829, as respects *Sarracenia;* and by Curtis in 1834, and Canby in 1868, as to *Dionæa;* and also, he might have added, by Dr. Lindley, in his "Ladies' Botany," published in 1834. In his introductory remarks Prof. Morren insists on the identity of the process of nutrition in the animal and vegetable kingdoms. The second portion of the discourse is devoted to the elucidation of the phenomena of "Motility" as exhibited in the irritability of the leaves of *Mimosa*, the stamens of *Berberis*, and other organs which exhibit similar peculiarities; the aggregation of protoplasm as seen in the "tentacles" of *Drosera;* the apparently spontaneous movements of zoospores, climbing plants, &c. Anyone desiring to obtain a general idea of what is at present known on these interesting subjects could not do better than consult Prof. Morren's lecture. It is pleasant to find a tribute to "la science Anglaise" in connection with vegetable physiology.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Supposed New Laurentian Fossil

When a man finds that he has made a mistake, the best thing he can do is frankly to acknowledge and explicitly to correct it.

I lose no time, therefore, in making known to the readers of Nature that the notice of a New Laurentian Fossil which I published in its columns three weeks since, was written under a complete misapprehension of the real nature of the body. So far from being calcareous, as I had been led to believe by the information I had received from the geologist who found the specimen, it proves to consist of alternating layers of felspar and quartz—the former simulating an organic structure like that of *Stromatopora*, and the latter occupying what had been supposed to be the cavities of that structure—together constituting what is known to petrologists as "graphic granite."

The conclusions I had drawn from a cursory examination of the sections first sent me by Mr. Thomson, instead of being confirmed by a more minute study of thinner sections, proved to be altogether untenable; what I had supposed to be piles of flattened chamberlets in the thickness of each lamella, turning out to be mere fissures in the felspar, arranged with extraordinary regularity; and what had seemed to be a vertical tubular structure, proving to be mere striation.

The examination of numerous sections of this body, and a comparison of them with sections of the "graphic granite" found in its neighbourhood, has now satisfied me that the former presents no other indication of organic origin, than is afforded by the *Stromatopora*-like disposition of its alternating lamellæ; and that this is so nearly approached in the latter, as to show that the agencies which produced the "graphic granite" were competent to have produced the supposed Harris fossil.

Whether these agencies were entirely inorganic, or whether the "graphic granite" itself may not be a metamorphic form of an ancient organic structure (metamorphoses nearly as strange having undoubtedly happened), is a question which is not at present to be decided by anyone's *ipse dixit*. When a petrologist shall have succeeded in *making* a graphic granite, he will be entitled to speak with assurance of its purely mineral nature.

It will doubtless be triumphantly urged by those who maintain *Eozoon* to be a "pseudomorph," that as I have had to confess myself completely mistaken in regard to the Harris specimen, I am just as likely to have been wrong in regard to the Canadian ophicalcite. To this I have simply to reply that my mistake in the present case has arisen entirely from undue haste, and has been corrected by my own more careful study; which has satisfied me of the *entire absence*, in the Harris specimen, of those Foraminiferal characters which seem to me unmistakably recognisable in the Canadian *Eozoon*.

In the memorable discussion at which I was present in Paris, on the flint implements found associated with the Abbeville jaw, it was the *entire absence*, on the surface of those worked flints, of the staining, the dendrites, the patina, and the wearing of the edges, characteristic of the genuine implements, which satisfied the English experts of the factitious character of the former. But, so far from anyone being led by this discussion to call in question the fashioning of the genuine implements by men coeval with the river-gravels of the Somme, it only brought out more fully the strength of that case, by showing what complete reliance might be placed upon the characters of antiquity which they presented. And so, in the present instance, the striking contrast in the microscopic appearances presented by two bodies bearing a close resemblance in general structure, seems to me only to bring out the organic characters of the one more decidedly, by comparison with the purely mineral characters of the other.

William B. Carpenter

Theory of Electrical Induction

I was hoping someone of eminence would tell us what he thought of the arguments of Prof. Volpicelli, or whether no clearer view of induction had been arrived at. Prof. Clerk Maxwell's letter of last week brings back the subject to its natural point of view to one whose ideas are based upon potential, but at the same time it leaves some points doubtful which have a particular bearing on the whole theory. Might I therefore be allowed to ask information from him, by explaining the ideas which have been impressed upon me about this, by reading his book "Electricity and Magnetism," though they are removed *toto cælo* from the ideas expressed by the phraseology of Prof. Volpicelli, and that of the usual text-books.

We know nothing of electricity except as a force. We may speak of it as a fluid, and use a corresponding terminology, but it is always measured as force. A conductor is a body in which

these forces immediately equilibriate themselves at the expense of calling into play other forces of the same or of opposite kind amongst the molecules of the dielectric. These forces give rise to the diminishing potentials as they are equilibriated over greater and greater surfaces. When another conductor is brought into the neighbourhood, since throughout it the electrical forces are in equilibrium amongst themselves, the various molecular forces are as before manifested only at the surface, and they are necessarily negative where the conductor obtrudes into regions of higher positive potential than its own mean, and positive where it lies in the regions of lower positive potential. But not only this, the molecular forces which keep the electrical forces in the dielectric in equilibrium cannot thus simply be pushed, as it were, backwards and forwards, but must fall into equilibrium in their own way—in other words there is a redistribution of electricity both on the inductor and inducer, which can only be determined by properly drawing the equipotential surfaces corresponding to the new arrangement (if possible). The state of stress of the particles of the dielectric surrounding any small conductor is not affected by its total motion of translation, except that as it is moved from the other conductors it is redistributed on the surface.

If now we draw a series of equipotential surfaces, that particular one which corresponds to the potential of the conductor will divide it, as Prof. Clerk Maxwell says, into two parts, on one of which is negative electricity, and on the other positive, in other words the state of stress of the particles outside the conductor is of one kind on one side, and of the opposite kind on the other. Now comes my first question. If this is the case how can it be said that there is either more positive electricity on the inducer nearest the inductor as Prof. Clerk Maxwell says, or less as Prof. Volpicelli says, than at the other end, when in fact there is none, but the force is negative? No doubt we can take for mathematical purposes a negative quantity as the sum of two others, one positive and the other negative and greater, but can the existence of the positive quantity be called a "fact" in consequence?

There is a way, however, in which we might be inclined to say that the positive electricity is least nearest the positive inductor, but this looked at in the same way as before, raises a second question. If we make a small conductor touch any part of the induced conductor, and then try it in the usual way, we might say that the spot on which we touched it when the small conductor was most electrified had the greatest amount of electricity upon it, and might determine its kind. But before doing this we ought to ask what will be the effect of bringing the new conductor into the neighbourhood, and this depends on its shape and size. The equipotential surfaces will all be altered, and the alteration may be such that the one belonging to the first induced conductor may leave the new one entirely on the positive or entirely on the negative side, or may divide it into two like the first induced conductor. In connecting with the earth we make the new conductor so large that the old one is all on the negative side; and the fact that by breaking contact we can keep the old conductor charged with negative electricity shows that we may take any smaller part from the wholly negative side and it will also show the same electricity, as in inductive machines. If the new conductor be so shaped or so large that it cuts through the neutral equipotential surface, on removing it only the balance of the forces called into play will be left to be equilibriated by the molecular forces, and that balance may be positive though the contact was on the negative side of the former neutral surface. In this way only could a finite conductor take positive electricity from the negative side, but in this case it is due to induction on the new conductor as temporarily forming part of the old, and not to the original induction on the first conductor. What experimental proof, then, is there, or can there be, if these principles are true, that there is *any* positive electricity nearest the positive inductor before the distribution is disturbed by too long or large a conductor being brought into the field? and how, therefore, is Melloni's theory true?

Also, might not a point if properly placed on the negative side, cut through the neutral equipotential surface and so discharge positive electricity?

I should be glad to know, from a good authority, that we may thus explain these phenomena by a reference to force alone and not to hypothetical fluids, and without meddling with such useful, perhaps, but unmechanical ideas as "bound" and "free."

J. F. BLAKE

Dynamometers and Units of Force

IN NATURE (vol. xiv., p. 29) Prof. Barrett says "it would be interesting to know on what grounds Prof. Hennessy bases his emphatic and reiterated assertion." The assertion referred to is contained in my former communication (NATURE, vol. xiii., p. 466). The grounds on which it is based are as follows:—In order to accurately measure units of force according to the C. G. S. system, spring balances which could be depended upon to the $\frac{1}{981}$ of a gramme or $\frac{1}{63}$ of a grain nearly would be required. In mechanics the forces to be compared and measured usually amount to several kilogrammes, and powerful spring dynamometers are most suitable for their estimation. Dynamometers such as those alluded to as being sent for exhibition from the College of Science to South Kensington are of this kind. By experiment I have found them unfit for the estimation of small units of force. I should be much interested in seeing Prof. Barrett or Dr. Ball measuring a C. G. S. unit or $\frac{1}{981}$ of a gramme by the aid of one of these dynamometers. It should be remembered that in this discussion I all through refer to these dynamometers and others of a similar kind employed in mechanics. I was already aware of the belief expressed by Sir William Thomson and Prof. Tait, that spring balances, "*if* carefully constructed," would rival or even surpass the ordinary balance. While thus referring to the possible perfection of the spring balance with the qualifying particle "*if*," they justly remark that the pendulum is the most delicate of all instruments for the measurement of force. A pendulum will probably always furnish the best means for measuring force in absolute measure, whether by large or small units; and I entertain strong doubts as to whether the spring balance can ever supersede the beam balance for accurate determinations of weight. In no department of experimental inquiry are such minute quantities weighed, and nowhere is greater accuracy in determining differences of weight required than in chemical analysis, and chemists almost universally employ the beam balance in preference to the spring balance in their most delicate analytical researches.

In my former communication I mentioned that the dynamometers alluded to could not be depended on within the tenth of a kilogramme. In saying this I have spoken of them in the most favourable terms, for the larger one can scarcely be depended upon within the fifth of a kilogramme.

Prof. Barrett quotes a statement as "occurring in Prof. Hennessy's own syllabus," which implies that I had adopted and used the C. G. S. system. The words quoted belong to a syllabus written by Dr. Ball for the session 1874–75. I entered on my duties after the commencement of that session, and my name was attached to new editions of the syllabus instead of the name of its author, while the part of the syllabus relating to mechanics remained untouched. I had been always under the impression that Prof. Barrett was perfectly aware that I was not the author of this syllabus, and although technically it might be regarded as the syllabus of applied mathematics in the College until a new one could be prepared and published with the sanction of the Science and Art Department, it seems scarcely correct in a scientific discussion to quote it as expressive of the views of a person who was well known not to be its author.

Prof. Barrett, in his first letter, laid much stress on the introduction of spring dynamometers into Dr. Ball's courses on mechanics for the estimation of force in absolute measure; as if such an employment of these instruments was entirely new. It is but just to observe that dynamometers of the same kind, and graduated in the same way, have been long since employed in other courses of mechanics, and such instruments are figured and described in some of the most common elementary books used in the colleges of Europe. With reference to the dynamical units which I prefer to employ in my courses of mechanics, Prof. Barrett uses the phrase, "a mixed system of kilogrammeters and foot-pounds." I never mix the two kinds of units. I keep them perfectly distinct. I employ both, because in the practical applications of mechanics, students may be called upon to apply one or the other. As far as I have been able to ascertain, these are the units in most general use among engineers throughout the world; and I should as soon expect mechanicians to adopt the C. G. S. system as to hear that bankers adopted our smallest coin as the unit of account instead of the sovereign, and to see the prices of stocks in the money market no longer quoted in pounds but in farthings.

HENRY HENNESSY

Royal College of Science for Ireland

THE POTATO DISEASE[1]

II.

THE Peronosporeæ are usually divided into two genera, viz.—Cystopus and Peronospora: with the former the potato disease has no connection.

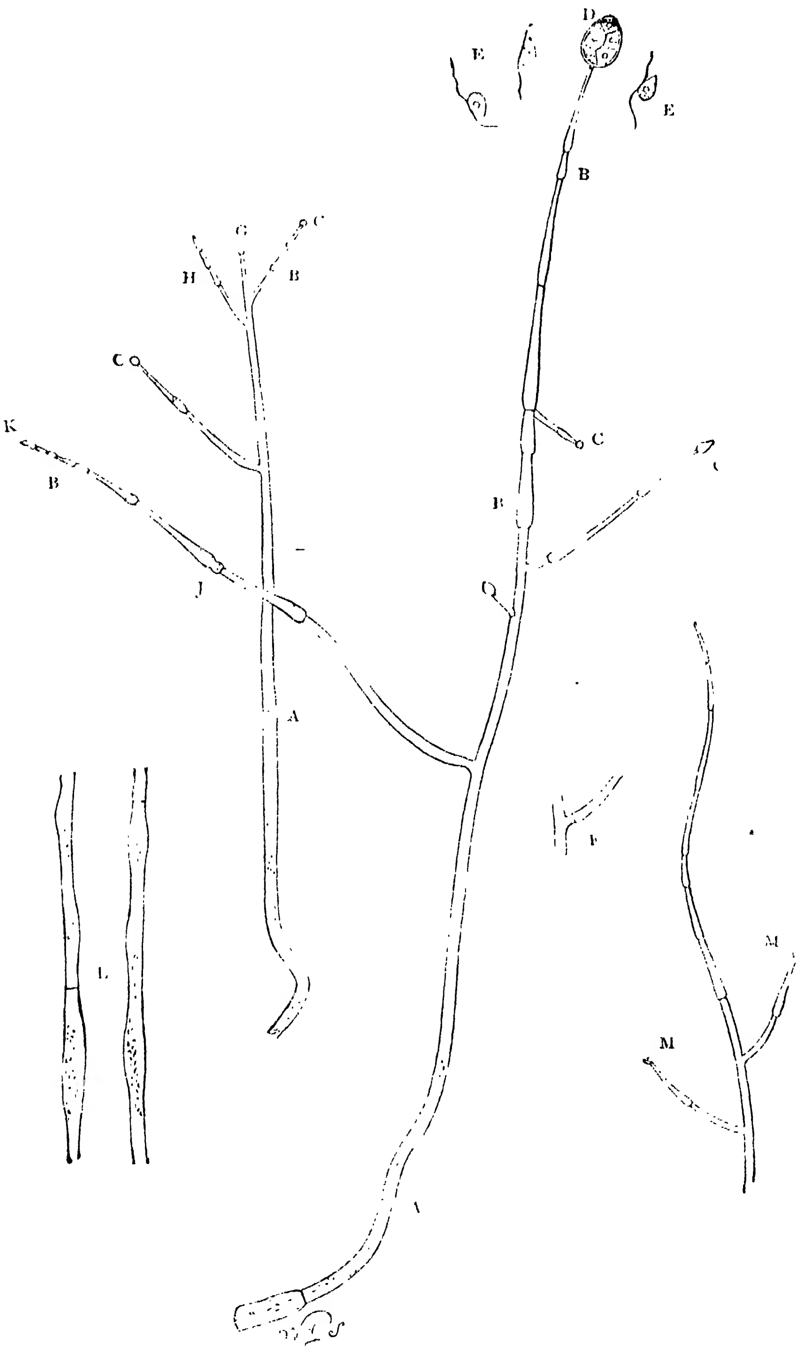

FIG. 7.—*Peronospora infestans*, Mont., × 250 dia. From De Bary's slide, No. III. A, A, septate conidiophores; B, B, vesicular swellings; C, C, immature conidia; D, conidium, showing differentiation of its contents; E, E, free zoospores; F, frequent mode of attachment of branch.

II.—PERONOSPORA, *Corda.*

The fungus of the potato disease was first placed under the genus Botrytis Mich., but Corda established Peronospora to receive the species with non-septate threads. Unfortunately for the genus, and for *P. infestans* in particular, the threads of the latter are always more or less septate, and this character effectually separates the potato-fungus from the *Saprolegnieæ* (as at present defined) where septa are unknown. De Bary now proposes the establishment of another new genus (under the name of Phytophthora) to receive the potato-fungus, the chief character of the proposed new genus resting on the development of, not one, but several spores (conidia) successively at the end of each branch of the aerial threads of the fungus (conidiophores). This character has been known to fungologists since the potato-fungus was first described, although it has generally been esteemed of specific rather than of generic value. The Rev. M. J. Berkeley in illustrating the potato-fungus for the Royal Horticultural Society, figures the conidia as being pushed off the branches (Pl. 13. Fig. 12*, 14). The same phenomenon is illustrated in the Micrographic Dictionary (Pl. 20, Fig. 6). I have also recorded the habit in the secondary condition of the fungus where the oogonia are successively pushed off the supporting threads.

As so much attention has of late been directed towards the Peronosporeæ it is more than ever necessary that the characters of the family should be correctly known, and this is especially important as regards the nature of the secondary state of these fungi: a brief statement of the sexual condition may therefore be useful. The female cells (oogonia) are borne sometimes on the tips of mycelial threads, sometimes as sessile bodies on different parts of the threads and sometimes intercalated within the threads themselves, after the manner of the illustrations on Figs. 1, 3, and 4. The male organs (antheridia) are usually smaller and carried on finer threads, not as a rule anatomically distinct from the oogonium-bearing threads. The contact of the antheridium with the oogonium, gives rise to the oospore or resting-spore.

Peronospora infestans, Mont., in its aerial state has been so often and so accurately described by Berkeley, De Bary, and others, that any further illustration or description is almost unnecessary. It must be confessed, however, that the figures first published by Messrs. Berkeley and Broome (in connection with Dr. Montagne) and latterly by De Bary, have only too many times been copied and recopied without reference to the fungus itself. There is therefore no apology required for publishing the present illustration (Fig. 7) which is new, and I trust exact. It is a camera lucida reproduction enlarged 250 diameters of a group of conidiophores as supplied by Prof. A. De Bary

[1] Continued from vol. xiii., p. 527.

to the Royal Agricultural Society, on their Slide No. III. (The three free zoospores are from a drawing by De Bary.) The septate aerial branches of the fungus, named conidiophores are seen at A A. The characteristic vesicular swellings peculiar to the potato-fungus at B B. Immature conidia at C C, and mature conidia at D, the latter showing the contents differentiating into zoospores. The zoospores are shown free at E E. The mycelium and conidiophores of *Peronospora infestans* are generally furnished with septa (A A) but this character is liable to great variation. The conidia are at first terminal (G) with no swelling on the thread below, but as the threads grow they push off the old conidia and continue to produce new ones on each newly formed apex. De Bary explains this phenomenon by saying, "When the first conidium is ripe, it is pushed to the side by an unequal swelling of the point to which it is attached. The top of this swollen portion then begins to grow in the original direction of the branch into a new conical point; and when this has reached a length equal to that of a conidium, or a conidium and a half, a new conidium is produced at the apex." I take this to be only partially correct, for the more reasonable explanation of the vesicular swellings on the threads is that the thread is constantly making an effort to produce new conidia, and each swelling is really an *abortive conidium*: each of these pieces will grow in water if free, as will the immature dust-like conidia (C C) the latter are being pushed off at M M. On looking at point B, it will be seen that the swellings there illustrated have never produced terminal conidia at all, but that each successive swelling is in itself an *attempt* to become one. Instead of these bodies *when terminal* growing to the length of "a conidium or a conidium and a half" they commonly remain the mere fourth or sixth part of a conidium in length, and often less, and never produce conidia. At J will be seen a double swelling: the first effort of the thread fell short, and the attempt to produce the conidium was renewed: such double swellings are common; a terminal one occurs at K. Vesicular swellings occur on all parts of the conidiophore; they are frequent at the base, commonly irregular as at L and always (to me) represent an attempt at fruit production.

It may just be well to remark that the suggestion as to the possibility of the oospores of *P. infestans* being ultimately found on some plant different from *Solanum tuberosum* is very old, and that Mr. Berkeley has recently found the potato-fungus growing upon the garden Petunia, this plant, we believe, has not been given in any previous list, and its importance must not be overlooked, for the Petunias come from the native country of the potato, one garden species even coming from Chili.

Prof. De Bary is not right in his surmise that he was "perhaps" the first to call attention to the perennial mycelium of the potato-fungus in 1863; Mr. Berkeley did this in 1846 and the fact has been confirmed by many observers since. The subject is thoroughly old and is discussed in our popular books; for instance—see vol. xiv. of the "International Series" Fungi (p. 156), where Dr. M. C. Cooke says, "The Peronospora of the potato is thus perennial by means of its mycelium." Most fungi depends for their existence upon "perennial mycelium." The "spawn" of the common mushroom is a good and well known example. A mycelium may however be perennial and yet produce oospores.

WORTHINGTON G. SMITH

OUR ASTRONOMICAL COLUMN

THE OCCULTATION OF SATURN, AUGUST 7, A.M.—Perhaps some observers who are provided with good telescopes may be induced to look for the occultation of the planet Saturn, on the morning of August 7, although (in the south of England) the immersion does not take place until half an hour after sunrise, and at emersion Saturn is only some five degrees above the south-western horizon.

Reference is made to the phenomenon here with the view to illustrate the use of the method of distributing predictions over a given geographical area, explained by Mr. W. S. B. Woolhouse in the *Companion to the Almanac* for 1871, as applicable to the phases of a solar eclipse, to the approximate prediction of the times of immersion and emersion of a star or planet in a lunar occultation, and the angles on the moon's limb at which they occur, at any place within the given area or very near to it. It is founded upon the assumption that the value to be determined is a linear algebraic function of the latitude and longitude of the place, for which the calculation is to be made. On this assumption the time (t), of any phase, &c., may be expressed thus:—

$$t = c + p.L + q.M.$$

where c, p, and q are three constants to be found.

If now direct calculations of the particulars of any phenomenon be made for three places moderately distant as Greenwich, Dublin, and Edinburgh, the constants will be determined by the substitution of the results, which supply the three equations of condition necessary. If the difference Greenwich—Dublin be called h, and Greenwich—Edinburgh k, then, as calculated by Mr. Woolhouse:

$$p = 0·1425\,h - 0·2840\,k$$
$$q = 0·05014\,h - 0·0213\,k$$
$$c = G - 1·4772\,k.$$

G being the result of the computation for Greenwich.
Also L is latitude − 50°, expressed in degrees and decimals.
And M is longitude from Greenwich, + if east, − if west, in minutes of *time* and decimals.

Applying this method to the occultation of Saturn we have, by direct computation for Greenwich, Dublin, and Edinburgh (astronomical times at Greenwich, Aug. 6).—

	Immersion.	Emersion.		Angle N Pt Immersion	Angle N Pt Emersion
	h m	h m			
Greenwich	17 7·3	18 3·10	..	94·0	331·1
Dublin	17 0·25	18 2·35	..	107·0	319·0
Edinburgh	17 0·25	18 2·38	.	111·2	313·6

The necessary data being taken from the *Nautical Almanac*, and the angles expressed as usual in that work.

Thus we find for Greenwich time of immersion and emersion at any place in this country, and for the angles on the moon's limb from north point

		h m	
Immersion	Aug. 6	17 0·05	[illegible] L [illegible] M.
Emersion	„	18 3·24	[illegible] L [illegible] M.
Angle Imm.		90·3	[illegible] L [illegible] M
Angle Em.		330·3	[illegible] L [illegible] 0·2 M

The differences between the results of these equations and direct calculations for Exeter and Liverpool are:—

	Exeter.	Liverpool.
	m	m.
Immersion	0·2	+ 0·2
Emersion	0·1	0·3
Angle Imm.	+ 0·3	0·2
Angle Em.	0·1	+ 0·1

In this manner have been derived the following particulars, as regards the occultation in question, which will illustrate the applicability of Mr. Woolhouse's method to such phenomena:—

	G.M.T. of Immersion	G.M.T. of Emersion		Angle from N. point Imm.	Angle from N. point Em.
	h m.	h m			°
Aberdeen	16 59·9	18 2·4	..	113	310
Cambridge	17 6·9	18 3·0		99	329
Exeter	17 5·6	18 2·7	..	96	. 331
Glasgow	16 59·4	18 2·3		112	. 312

NEW RED STAR.—Mr. Birmingham, Millbrook, Tuam, mentions (*A. N.*, 2,092) his having remarked an intensely red star, 8·5 magnitude, which is not in Schjellerup's catalogue (*Vierteljahrschrift der Astron. Gesellschaft*, ix. Jahrgang, Heft 4). From the approximate position given the star appears to be No. 3,168, + 36° in *Durchmusterung*, where it is also estimated 8·5, and its position 1855·0 is R.A. 18h. 27m. 19s., N.P.D. 53° 7′. It has not been found in any other catalogue.

THE DOUBLE STAR Σ 3,121.—This object well merits the attention of observers who are in the possession of large telescopes. Baron Dembowski seems to have given it up for the present as beyond his instrumental means. It is evidently a binary of no long period. For comparison we have—

Struve ..	1832·31	Position	20°·0	Distance	0″·85
Dembowski..	1866·22	,,	180·7	,,	0·68
,,	1872·23	,,	210·5	,,	a wedge
,,	1875·31	,,	252·0	,,	oval.

The place of this star for 1876·0 is in R.A. 9h. 10m. 32s., N.P.D. 60° 53′·8.

THE LOAN COLLECTION CONFERENCES.

THE work in connection with the South Kensington Conferences has been carried on heartily and successfully during the past week. The number of visitors to the collection has been, all things considered, satisfactory, and the conference-room is always well filled.

Of the papers in the Section of Mechanics read on the 17th inst., M. Tresca's, on the "Flow of Solids," possessed some novelty and interest. From his experiments he drew inferences as to the proper form and mode of application of tools, explained the theory of many of the adjustments which workmen have found out by rule of thumb, and indicated extensions of the use of the principles now reduced into formulæ. He added that, in his belief, these mechanical laws ought to be pursued into physiology, and that the accretion of cell to cell was a mechanical phenomenon.

The conversazione given by the Physical Society the same evening was brilliant and successful.

At the meeting of the Chemical Section last Thursday, Dr. Frankland gave a long and highly important address, mainly on eudiometric apparatus. This address we give this week *in extenso*. Dr. J. H. Gilbert, F.R.S., then gave an interesting lecture on "Some Points connected with Vegetation." Mr. W. F. Donkin, M. A., then gave a description of the ozone apparatus of Sir B. Brodie, Bart., F.R.S., after which Prof. Andrews, F.R.S., concluded the meeting with an account of some experimental investigations in connection with the physical constitution of gases.

On Friday was held the second Conference in connection with the Physical Section. The conference-room throughout the day was unusually well filled. The first communication was from Prof. Tyndall, F.R.S., on the "Reflection of Sound." With the help of Mr. Cotterell, his assistant, he reproduced some of the experiments with sensitive flames with which he has made scientific audiences so familiar.

Dr. Stone spoke on the subject of "Just Intonation and the Limits of Audible Sound." Mr. R. H. M. Bosanquet, M.A., spoke on "Instruments of Just Intonation," and explained the construction of the enharmonic harmonium contributed by him to the collection.

Mr. F. Galton, F.R.S., in his remarks "On the Limits of Audible Sound," spoke of experiments which he had been trying for some time past on the susceptibility of various animals to the highest notes, such as those of extremely small whistles. He had arrived at the conclusion that no animals were so sensitive to sounds of the character in question as cats, which, of course, were the animals produced by natural selection to prey upon those other animals which in nature produced such sounds—namely, mice.

Prof. W. G. Adams, F.R.S., spoke on the late Sir C. Wheatstone's acoustical discoveries, and Mr. W. Chappell followed with a discourse "On Ancient Musical Science."

Mr. J. Baillie Hamilton spoke on Æolian instruments. He gave a history of the attempts in Europe to combine wind and string, and coming down to the present time he spoke of his own experiments. He has found that a metallic ring of suitable elasticity well supplies the place of a string's constraint on a vibrator. Variations in the shape of the ring produce differences of tone. Thus, passing from the circle to almond-shaped rings, all qualities from the flute to the horn are created.

M. Tresca referred to the still existing monuments of the history of science. For various reasons, want of appreciation, want of care, &c., many instruments of historical interest are lost. France is relatively well off in its historical instruments, and it is well represented in this exhibition. M. Tresca then referred to the instruments in the collection France has sent over, giving a graphic sketch of their history and the history of the progress of the sciences they have helped forward. The Earl of Rosse, F.R.S., made a brief communication on the thermopiles which he is now using in connection with the telescopes belonging to the late Earl, after which Mr. De la Rue described his electric batteries of a novel construction. The Cavaliere Prof. De Eccher made a communication on the instruments sent over from Italy.

The conversazione given by the Geographical Society on Saturday evening was in all respects a successful one; more than 2,000 persons accepted the invitations sent out.

In the second meeting of the Mechanical Section on Monday, the first paper was by Prof. Kennedy, on "Reuleaux's Collection of Kinematic Models." Prof. Kennedy explained the general principles and some of the details of these educational models designed by their constructor for the illustration of the theory of machines. Mr. W. Barnaby, C.B., then read a paper on "Naval Architecture," which we hope to publish in our next number. Mr. W. Froude, F.R.S. then gave a short lecture on "Fluid Resistance," detailing many of his experiments. The other papers read were by Mr. Thomas Stevenson, on "Lighthouses," M. le Général Morin on "Ventilation," Messrs. Dent on "Time-measurers," and Mr. J. N. Douglass, C.E., on "Instruments contributed by the Trinity House."

The Chemical Section met again on Tuesday. The President, Dr. Frankland, F.R.S., read a communication from M. le Professeur Frémy, the French Chemist, on the Diminution of Scientific Research. M. Frémy has founded and carried on during the last twelve years a laboratory for the prosecution of original investigations by students who have completed their scientific studies. The experience which he has gained is such as to lead him to the conclusion that it is necessary to invoke state aid in order to restore research to that position which it should occupy. As the State chooses its officers and engineers after a severe course of study, and then ensures their regular advancement in its service, M. Frémy claims a similar boon on behalf of pure science, which renders such invaluable services to the community. He proposes that the scientific service should consist of five grades, with salaries rising from a minimum of 120*l*. to 800*l*. per annum, and that the fitness of candidates for entrance to it should be decided by a jury of men of acknowledged scientific reputation, independence, and integrity. This jury should make known in official reports the claims of the various candidates to advancement, thus securing public criticism, and removing all opportunities of intrigue or favour. Prof. Roscoe, F.R.S., then gave a lecture on Vanadium and its Compounds, exhibiting on the table the collection of these substances

contributed by himself to the Loan Collection, representing the results of his admirably conducted series of researches in connection with this particular one of those metals designated by the chemist as "rare." The President, in thanking Prof. Roscoe, remarked, in reference to the value of scientific research, that it could not be too widely known that all the greatest results to which it had conduced had been obtained primarily by devotion to purely abstract science—practical applications having unexpectedly followed upon discovery. Prof. Guthrie, F.R.S., then gave an account of his researches on "Cryohydrates and Water of Crystallisation," a subject on which he has been working for the last three years. Prof. Williamson, F.R.S., gave an address on the "Manufacture of Steel," limiting his attention chiefly to the modes devised for the obviation and repression of the escape of carbonic oxide gas from molten steel during the casting and cooling process, after leaving the Bessemer or Siemens-Martin furnace. Mr. W. C. Roberts, F.R.S., subsequently read a paper, on the "Apparatus used by the late Prof. Graham in his Researches." The principal interest attaching to these pieces of apparatus was the simplicity of the means by which the late Master of the Mint established such important discoveries as the law of the diffusion of gases, the principle of the endosmotic action of fluids, and the consequent division of chemical substances into crystalloids and colloids. Mr. W. N. Hartley read a paper on the existence of "Liquid Carbonic Acid in the Cavities of Crystals," Dr. Gladstone, F.R.S., following with a short address on the electrolysis of organic compounds with the copper zinc couple. Dr. Frankland, in closing the Chemical Conference, congratulated the audience upon the success which had attended the proceedings throughout the two meetings.

Yesterday the Section of Physics met for the third time, when the following papers were to be read:—

Prof. J. Clerk Maxwell, "On the Equilibrium of Heterogeneous Bodies;" Prof. Andrews, "On the Liquid and Gaseous States of Bodies;" M. Sarasin-Diodati, "On M. de la Rive's Experiments in Statical Electricity;" M. Lemström, "Sur l'Aurore Boréale;" Baron F. de Wrangell, "On a New Form of Voltameter;" Il Commendatore Professore Blaserna, "Sur l'état Variable des Courants Electriques;" Mr. Warren de la Rue, "On Astronomical Photography;" Mr. Ranyard, "On the Instruments lent by the Royal Astronomical Society;" Mr. Brooke, "On Magnetic Registration, and on the Corrections of the Magnetometers;" Prof. Carey Foster, "On Electrical Measurements;" Herr Prof. Dr. Rijke, "On the Historical Instruments from Leyden and Cassel;" the Rev. R. Main, "On a Telescope of Sir W. Herschel's."

The third meeting of the Mechanical Section is held to-day.

The first meeting in the Section of Biology will take place to-morrow, when the following papers will be read:—Dr. J. B. Sanderson, the President, "On Methods of Physiological Measurement and Registration;" Prof. Marey "On various Instruments for Investigating and Registering Vital Movements;" Dr. Hooker "On the Plan of the New Laboratory for Investigations relating to the Physiology of Plants at Kew;" Prof. Dyer "On various Apparatus for Investigating and Registering the Growth of Plants contributed by the Physiological Laboratory of Bremen;" Dr. P. L. Sclater "On Drawings contributed by the Zoological Society;" Dr. Brunton "On a new Myographic Apparatus;" Dr. Klein "On Recording Apparatus exhibited by the Physiological Institute of the University of Prague;" M. E. A. Schafer "On recent Improvements in Recording Apparatus."

The Science and Art Department are organising a series of popular lectures to be given on the evenings of the free days. Demonstrations of the objects in the galleries are also now given by the exhibitors or other competent persons at frequent intervals during the day.

SECTION—CHEMISTRY.

Opening Address by the President, Dr. Frankland, F.R.S.

THE Conference which I have been requested to open to-day has for its object the discussion of the merits and defects of the various forms of chemical apparatus exhibited in these buildings; and the criticism of the original investigations which are here illustrated, partly by the instruments used in them, and partly by the chemical compounds, to the discovery of which they have led.

Various objects interesting to chemists have been displayed in former international exhibitions, but it may be safely asserted that such a collection as this, which has been brought together in these buildings, has never before been seen; neither has there before been the opportunity for discussion and criticism, by men eminent in science from all parts of Europe, which is now afforded.

Such a collection of apparatus and products, gathered from all parts of Europe is useful in disclosing, to chemical investigators and others, the best sources whence to procure apparatus; it is interesting historically and as showing the improvements in chemical apparatus during the present century; and it is instructive in the comparisons it affords of the various forms of instruments used for the same purpose in different countries, and by different experimenters.

The entire novelty of such a collection as that belonging to this section has rendered the attainment of the object sought for, on the present occasion, exceedingly difficult. The workers in science have hitherto had no inducement to preserve the *instruments* with which they experimented. When an investigation was finished the apparatus employed was dismantled and converted to other uses. Still less inducement has there been to preserve the *chemical compounds* resulting from research, although their creation required, in many cases, a great expenditure of time and labour. The chief object of preparing such compounds has hitherto been, in most cases, merely to ascertain their existence, to show their molecular relations to previously known bodies, and to ascertain a few of their leading properties such as colour, specific gravity, vapour density, melting point, boiling point, and chemical composition. They have been weighed and measured and then dismissed out of existence. And thus the present collection of chemical preparations is but the merest skeleton of a complete exposition of all known chemical compounds.

It is, indeed, remarkable, that whilst *natural* chemical compounds are exhibited in almost endlessly multiplied specimens in the mineralogical collections of our national museums, the *artificial* compounds which have resulted from research, or have been the foundation of important theories and generalisations, have nowhere been honoured by admission into national collections. The neglect, not to say contempt, with which these productions of the laboratory have been treated, cannot be justified on the ground of their want of national utility. It is true that from an exclusively commercial point of view, no one of them can lay claim to the importance of coal, iron, silver, and gold. Still, many of them, such as the paraffins, the coal-tar colours, and many of the compounds of sulphur, potassium, sodium, and ammonium, have contributed, in an important degree, to the wealth and prosperity of this and other states. Had these artificial compounds remained undiscovered, how different would now have been the condition of the industries of bleaching, dyeing, calico printing, glass-making, and the manufactures connected with the production of artificial light. Many of these artificial compounds have become of the most essential importance to the physician, the artist, the telegraphist, the engineer, and the manufacturer, and it cannot be doubted that many more would soon come into active service for such purposes if they were better known.

But not alone on the ground of utility and incentive to the further useful discovery of technical applications would I plead for the establishment of national museums of chemical preparations; such collections would be of the highest interest both to the student and the investigator. They would call vividly before the mind the results of labours which can only otherwise become known by a tedious search through the transactions of learned societies. An intelligent study of a properly arranged collection of artificial chemical compounds would show the progressive triumph of mind over matter—not over masses moved by mechanical agencies—for monuments of this the engineer and the architect need only bid the inquirer, in the language of Wren's tablet, to "look around him"—but over the ultimate atoms which, in these compounds, are compelled to submit themselves to the will of man, and to form new structures, seen only, in most cases, by the discoverer himself, and the qualities and uses of which are but very imperfectly ascertained. Nine-tenths of these compounds are no better known than islands which have been seen only from the deck of a ship and whose position has been accurately marked upon a chart. But a collection of them, if properly kept up, would represent the actual condition of our knowledge of chemical facts, and, if properly arranged, would suggest to the observant student the direction of future investigation.

I know of no other incentive to research which would be more likely to call original inquirers into existence. The student wishing to commence a chemical investigation is always confronted at the outset by the difficulty of finding the boundary line between the known and the unknown, and this difficulty must obviously increase from year to year owing to the continued expansion of the circle of knowledge. It has led to a suggestion emanating from the British Association, that chemists who are intimately acquainted with particular departments of their science should suggest subjects of research for the benefit of students. Much may be said no doubt in favour of such a scheme; but it appears to me that the development of original talent in the young investigator would be more surely promoted by giving him the means of selecting for himself a subject for experimental inquiry, rather than by inducing him to follow the less invigorating plan of working out the suggestions of others. I venture, therefore, thus prominently to call attention to the non-existence, in any country, of a museum of artificial compounds, and to the great value, both economical, scientific, and educational, which such a museum would possess. I feel convinced that if such museums were established in the capitals of Europe, chemical investigators throughout the world would gladly contribute their new products to them, and thus keep them abreast of the discoveries of chemical science.

Amongst the groups of objects in the Chemical Section, not the least interesting is that which consists of *Apparatus and Contrivances employed in the Generation and Application of Heat.* The great advances which have been made in the modes of producing and applying heat for chemical purposes are strikingly conspicuous. The cumbrous furnaces of the earlier operators, constructed in fireproof vaults, have gradually been replaced by simple and elegant contrivances, which would scarcely look out of place upon a drawing-room table. The time is still fresh in the recollection of many of us, when the fusion of a silicate for quantitative analysis, or the heating to redness of oxide of copper for the combustion of an organic compound, required in each case the expenditure of much time and trouble in the lighting of a coke or charcoal furnace. Now these operations are performed in small gas furnaces with or without air blast. Conspicuous amongst these inventions are the gas-burners of Bunsen and Hofmann, the oxy-coal gas furnaces of Deville, the blast gas furnaces of Griffin, and the hot blast gas furnaces of Fletcher. Of these fundamental inventions many ingenious modifications for special purposes have been devised, amongst which I may mention the valuable contrivances of Finkener, Mitscherlich, Wallace and Muncke. The blast gas-burners of Hofmann and Bunsen, the blast gas-furnaces of Deville, Griffin, and Bunsen, and the furnaces for organic analysis by Hofmann, Bunsen, Finkener, Mitscherlich, and Muncke, are amongst the exhibits illustrating the application of heat in chemical operations.

These burners and furnaces command a range of temperature from the gentlest ignition up to the most intense heat procurable by chemical means; but the temperature produced by such combinations as those of oxygen and hydrogen, or oxygen and carbon, enormously high though it be, now no longer suffices, and recourse must be had to the still more intense heat of the electric discharge. The electric current and the stream of sparks are now not unfrequently called into requisition by the chemist, and from this point of view the electric lamp and the apparatus of Hofmann and others for the decomposition of gases by the spark-stream must be classed with chemical furnaces.

To apparatus for the application of heat belong the various forms of water, steam, and air baths, or drying closets. Convenient contrivances of this class invented by Bunsen, Mitscherlich, Habermann, and Muncke, are exhibited by Messrs. Warmbrunn, Quilitz and Co, Mr. Johann Lentz, and Mr. Julius Schober all of Berlin, and by Mr. C. Desaga of Heidelberg.

In the application of gas to chemical purposes, regulators of pressure and temperature are often of the utmost importance, in order that operations requiring the prolonged and regular action of heat may not require the constant attention of the operator. The ingenious and effective contrivances of Bunsen and Kramer, for this purpose are exhibited.

Closely connected again with appliances for raising temperature are those intended for its reduction—the refrigerators or condensers.—The Liebig's condenser is still the refrigerator almost exclusively used, but few pieces of apparatus have been so much modified and refined, as will be seen on comparing the original design with the present construction—the final light and convenient form having been given to it by my late friend Mr. B. F. Duppa. Most manufacturers of chemical apparatus exhibit various forms of this condenser.

Sprengel Pumps.—Of the comparatively recent appliances for facilitating chemical work, few can lay claim to higher merit than the invention of Dr. Hermann Sprengel, in the year 1865, for the production of vacua by the fall of liquids in tubes; and yet this invention remained for many years dormant, until the late Master of the Mint applied the mercurial pump to the extraction and collection of occluded gases, and Bunsen the water-pump to hastening the filtration of liquids. Without the mercurial pump the elements of the organic matter in potable waters could not be determined, and the highly interesting results which this pump has quite recently achieved in the hands of Mr. Crookes, come home to every one who has seen the various forms of the radiometer.

Bunsen's application of the water-pump to filtration has done much to shorten one of the most tedious and troublesome operations of gravimetrical analysis.

Dr. Sprengel's invention has, moreover, nearly abolished the use of the air-pump in chemical laboratories, and I need not therefore, perhaps, bring under the special notice of this section the various improvements in air-pumps which are illustrated by the exhibits in the Physical Section.

Models, diagrams, apparatus and chemicals used in the teaching of chemistry, include numerous exhibits of great interest. It is to be regretted, however, that models and plans of chemical laboratories are not more numerously represented. The important improvements which have been introduced of late years, and the numerous laboratories of truly palatial proportions which have been built,

in almost every case at the cost of the State, would have rendered a complete exposition of their plans and fittings most instructive and interesting. Dr. de Loos, has, however, sent us a model of the chemical laboratory in the secondary Town School of Leyden. And we have from Mr. Waterhouse plans of the Owens College laboratories in Manchester. The latter were devised after the professor of Chemistry and the architect had visited all the great laboratories of Europe, and for compactness, economy of space, appropriateness of fittings. and ventilation, they are unsurpassed.

In illustration of the permanent fittings of laboratories we have from the Chemical Institute of the University of Strassburg a diagram showing elevation, section, and plan of a "digestorium," or iron closet, for use in dangerous operations in which explosions are liable to occur. This is a contrivance which ought never to be absent from a laboratory in which research is carried on.

Prof. Roscoe exhibits a beautiful and effective series of diagrams and models illustrating the processes carried on in alkali works, and Mr. Henry Deacon a sectional model of his ingenious apparatus for exposing porous materials and currents of gases to mutual action.

Dr. de Loos, of Leyden, has sent drawings of gas works used for teaching technical chemistry in secondary schools.

We are indebted to Mr. Spence, of Manchester, for a series of specimens illustrating his process for the manufacture of ammonia-alum. To Messrs. Roberts, Dale and Co. for specimens illustrating the manufacture of oxalic acid. To Messrs. Calvert and Co. for similar illustrations of the manufacture of carbolic, cressylic and picric acids.

Messrs. Hargreaves and Robinson exhibit plans and specimens in connection with their new process of manufacturing sulphate of soda directly from sulphurous acid, steam, air, and salt; whereby the intermediate production of sulphuric acid is avoided. A chemical factory is generally conspicuous in the landscape by a series of huge and ugly leaden vitriol-chambers. Should the new process prove as successful as the inventors anticipate, these leaden chambers will almost entirely disappear, and the aspect of chemical factories will undergo a more profound modification than any which has occurred during the last half century.

The splendid platinum apparatus of Messrs. Johnson and Matthey for the concentration of sulphuric acid, will also contribute much to compactness in chemical works, by the abolition of cumbrous leaden pans and long ranges of glass retorts.

Not only is the sense of sight thus likely to be relieved, but that of smell, which, in the case of chemical works, is perhaps of even more importance, is also gradually being subjected to less offence by the adoption of Mond's process for the recovery of sulphur from soda-waste. The vast mounds of this material which surround alkali works, not only pollute the air with sulphuretted hydrogen; but also the neighbouring streams, with an offensive drainage which is very destructive to fish life. Herr Mond has succeeded in profitably extracting the sulphur—the offending constituent of the waste—and Messrs. John Hutchinson & Co. of Widness, exhibit specimens illustrating this important process.

Dr. Van Rijn, of Venlo, Netherlands, exhibits fine crystals of potash and chrome alums. One of the Octohedrons of potash alum weighs no less than 11 lbs.

Messrs. W. J. Norris and Brother of Calder Chemical Works have sent specimens useful in teaching the technology of lichen colours, sulphate of alumina, and bichromate of potash.

Messrs. Brooke, Simpson, and Spiller contribute a fine series of specimens illustrating the technology of coal-tar colours.

Lastly, several magnificent series of specimens have been sent over by members of the German Chemical Society.

They comprise, firstly, some items of much historical interest. Thus, we have from Prof. Wöhler the first specimens of boron and aluminium ever prepared. And, from the same chemist, another historical specimen which, it is no exaggeration to say, is the most interesting now in existence, for, after the discovery of oxygen, it marks the greatest epoch in chemical science. I allude to this specimen of the first organic compound prepared synthetically from its elements by Wöhler, without the aid of vitality. If the work of the army of chemists who have successfully attacked the problems of organic chemistry during the last quarter of a century were to be described in one word, that word would be SYNTHESIS. In this specimen of urea we have then the germ of that vast amount of synthetical work which has done so much to dispel the superstition of vital force and to win for chemistry the position of an exact science. In the absence of a specimen of the first oxygen from Priestley's laboratory in 1774, it seems to me that this specimen of the first synthesised urea made in 1828 is, historically, the most interesting chemical the world has to show.

Secondly, we have a beautiful collection of all the compounds discovered by Liebig, but I need not dwell upon them, as they have been so recently described by their exhibitor, Prof. Hofmann, in his Faraday lecture delivered to the Fellows of the English Chemical Society.

And thirdly, there are several interesting series of specimens illustrating the researches of Biedermann, Weltzien, Michaelis, Hübner, Hofmann, Lieberman, Oppenheim, Pinner, Wichelhaus, Tiemann, and others.

We come now to a review of that sub-division of the Chemical Section which illustrates original research, viz., chemical compounds discovered in certain specific investigations, and apparatus used in the prosecution of research. Whilst the sub-division which I have been describing illustrates for the most part the training of the young chemist in habits of observation and in the use of apparatus and processes, the one we are now considering aims at representing, so far as it can be objectively represented, the highest outcome of this training—the additions to our knowledge acquired through the accurate methods of observation and experiment which it is the function of the chemical instructor to teach. I have already remarked on the interest and importance of exhibits of this class, and it is to be regretted that out of so many chemical investigators so few have exhibited. It is characteristic of the direction long taken by chemical research, that of about 25 exhibitors only two have contributed mineral as distinguished from organic products.

Prof. Roscoe exhibits sixty-five compounds of vanadium discovered and investigated by himself. This classical research stands out as a model of thoroughness, and not only clearly discloses the habits of a comparatively rare metal, but brings to light some new and interesting facts in connection with the theory of atomicity. As Prof. Roscoe has consented to deliver an address on these compounds, we shall have an opportunity of discussing the peculiarities and anomalies which have presented themselves in the course of this investigation.

The water of crystallisation of salts has been the subject of some controversy amongst chemists of late. It is generally considered to be present in atomic proportions, however complex these may sometimes be, and most chemists are inclined to regard the bond of union between this water and the salt proper in the light of a *molecular*, as distinguished from an *atomic*, attraction. Mr. Walcott Gibbs, however, has recently endeavoured to show that the union is strictly atomic, and subject to the ordinary laws of atomicity. The subject has attracted the attention of Prof. Guthrie, who has attacked it from a new side, and obtained results which throw much light on this question. He has promised to give us an address on the subject at the next Chemical Conference. Prof. Guthrie also exhibits—

Nitroxide of Amylene.—Discovered by the exhibitor. Of historical interest as being the first instance in which nitroxyl NO_2 was shown to behave as a halogen in uniting directly with an olefine to form a body homologous with "Dutch liquid." The composition of the body is $C_5H_{10}(NO_2)_2$.

Sulphide of Œnanthyl.—Discovered by the exhibitor, and of historical interest as being the first instance in which a term of a higher alcohol series was made from terms of lower alcohols. It is formed by the action of zinc ethyl on sulpho-chloride of amylene.

And Nitrite of Amyl.—Discovered by M. Balard. Its therapeutic action was discovered, and its introduction into the pharmacopœia recommended, by the exhibitor; and it is now coming into use in tetanic and other nervous affections.

A series of twenty-three specimens of hydrocarbons derived from Pennsylvanian petroleum is exhibited by Prof. Schorlemmer. They form a striking record of the skill with which a most laborious and difficult investigation has been conducted.

Very interesting and important are the ethyl compounds derived from the isolated radical methyl exhibited by Mr. W. H. Darling. The results of some experiments made by myself seemed to indicate that the products of the action of chlorine upon methyl were not ethyl compounds; but the experiments of Schorlemmer and Darling, conducted with much larger quantities of material, show that my conclusion was erroneous. Mr. Darling exhibits ethylic chloride, ethylic alcohol, ethylidenic chloride, and sodic acetate, all made from electrolytic methyl.

Mr. Perkin has sent a large collection of specimens illustrating his researches on mauveine, artificial alizarin, artificial coumarin, glyoxylic acid, and other subjects. His investigation of glyoxylic acid seems to have at last put an end to the controversy as to the possibility of two semimolecules of hydroxyl being united with one and the same atom of carbon. I will not, however, anticipate Mr. Perkin, who will, I trust, personally give us an account of his researches.

Amongst the other exhibits in this department are numerous and important contributions from the laboratories of St. Petersburg, Louvain, and Edinburgh. For several years past chemical research has been actively carried on in Russia.

The apparatus of research exhibited in the Chemical Section has suffered much from the depredations of the physicists, for although chemistry is essentially founded upon measurements of weight and volume, the instruments used for such determinations have been swept almost *en masse* into the section of measurement; nevertheless, the chemical section contains several objects of unusual interest. The apparatus with which chemists both ancient and modern prosecuted their researches was generally of a simple description, and often dismantled as soon as the necessary operations were completed; consequently it was far less likely to be preserved than the more expensive and elaborate contrivances of the physicist. Here, however, is Black's balance, presented to the Science and Art Museum of Edinburgh by the Right Hon. Lyon Playfair. Upon this balance Dr. Black ascertained in 1755 the loss of weight suffered by carbonate of magnesia and limestone when exposed to heat. Hales previously used a balance for this purpose, but the instrument before us was certainly one of the first employed for quantitative chemistry. The balances used by Cavendish, Davy, Young, and Dalton are here, and each one of them has its own historical interest for the chemist. The balance of Cavendish is probably the instrument with which in 1783 or 1784 he first ascertained that a globe filled with a mixture of oxygen and hydrogen gases underwent no alteration in weight when the mixture was exploded.

From gravimetric instruments we are naturally led to volumetric apparatus used in quantitative chemistry, and I will now, in conclusion, briefly direct the attention of the conference to apparatus used in the analysis of gases, in the hope that a discussion of the merits and defects of the numerous instruments now before me may have the effect of directing a larger share of attention to eudiometric chemistry than has hitherto been accorded to it. This branch of chemical analysis originated in the attempts of Fontana, Landriani, Scheele, Priestley, Cavendish, Gay-Lussac, Dalton, and others, to determine the volume of oxygen in samples of atmospheric air taken from various localities. In these primitive instruments air was exposed to the action of some substance either solid, liquid, or gaseous, which combined with the oxygen and left the nitrogen unacted upon. The chief substances used were phosphorus, potassic sulphide, nitric oxide, a solution of nitric oxide in ferrous sulphate, and a mixture of sulphur and iron filings. Many of these instruments were of simple or even rude construction, and little calculated to inspire confidence in the results. Nevertheless, the accuracy of a determination often depends much more upon the skill of the operator than upon the construction of the instrument used; and thus Cavendish, with nitric oxide as his reagent and water as the confining liquid, made many hundred analyses of air, collected in various localities, in 1781, and found the percentage of oxygen to be invariably 20.83, a number nearly identical with those obtained by Bunsen and Regnault with much more perfect means. But the average chemist of that day obtained the most discordant results with the same apparatus and materials, and would doubtless also do so at the present day. By improved apparatus and methods the work of the average chemist is made to equal, or nearly so, that of the most skilful.

Volta introduced a new reagent, hydrogen, for the determination of oxygen, and he was the first to employ the electric spark in eudiometry. The use of mercury instead of water for confining the gases eliminated the source of fallacy caused by transfusion through the latter liquid, and lastly Bunsen, in the year 1857, brought Volta's eudiometer to its highest degree of perfection.

The President then proceeded to describe and criticise the various forms of apparatus for the analysis of gaseous mixtures, and concluded as follows:—

Such are the modern developments of the eudiometer now at the disposal of chemists. For rapidity of working and delicacy of measurement they leave nothing to be desired; indeed, as regards delicacy it may be doubted whether amongst all the instruments for measurement in this exhibition, there is one which can, like some of these eudiometers, give a distinct value in weight or volume to the one fourteen millionth part of a gramme of matter. Their drawback is their fragility, and any modifications to diminish this would doubtless be welcomed by chemists, since, chiefly for these reasons, eudiometry is still very rarely practised in chemical laboratories.

THE PRESS ON THE LOAN COLLECTION

IN continuation of our article in last week's number we proceed to give a few more selections from the principal organs of public opinion, indicative of the light in which they regard the scientific collection which has been brought together at South Kensington. Last week we confined ourselves mainly to the daily press; this week we are able to cull the opinions of the principal weekly papers. Public opinion as thus expressed, it will be seen, all but unanimously approves of the collection as creditable to its organizers and to the country at large, as beneficial to the progress of science, and as calculated to have an important educative influence on the British public. We think the collection of public opinion as thus expressed will serve a good purpose. It will show to those men of science who have been more or less connected with the

organization of the Loan Collection that their efforts have met with the approval of the intelligent and unprejudiced portion of their non-scientific fellow-countrymen, that these efforts have been unexpectedly successful, and that public opinion points to a permanent successor as the natural outcome of this temporary collection.

The *Saturday Review* seldom gives way to unmeasured approval of any human effort; it is therefore extremely gratifying to find so severe a critic having nothing but praise to bestow on the collection. The following are a few extracts from last Saturday's number:—

"Mr. Spottiswoode, in his address as President of the first of the Conferences which have been arranged in connection with the Loan Collection of Scientific Apparatus at South Kensington, said that he was disposed to regard this Exhibition as marking an epoch in the history of science; and there are undoubtedly reasons why it may be expected to exercise a deep and beneficial influence on the prospects of scientific culture in this country. We have here brought together, not only a collection of remarkable instruments from all parts of the civilized world, and representing almost every school and period of research, but also a numerous gathering of the men who are at the present moment engaged in extending still further the range of discovery, and the practical application of its results. It has often been a reproach against this country on the part of foreigners that it is indifferent to science except in the forms in which it can be turned to immediate commercial profit; and this criticism, though unjust to the heroic self-sacrifice which has characterised many of our leading scientific pioneers, must be admitted to be in a certain degree true as to the general attitude of the public. . . . . In this country the Executive usually hesitates to do anything unless there is a strong pressure of opinion, and it is tolerably certain that science will have little to hope for from that quarter until it has the public at its back; and it is to it, therefore, that an appeal should be made. It may be hoped that the present Exhibition will be the beginning of a movement of this kind. The fact that it is opened under the auspices of a Government department would seem to show that there is not wanting a certain sympathy on that side; but whether any large, substantial measures will ever be taken, will chiefly depend on the interest which such a presentation of science excites among the community at large. Again, an Exhibition of this kind is useful in bringing to light the actual operations of the scientific world, the problems which have been solved, and those others which are still in a nebulous condition, with just here and there a clue peeping out; and thus the interchange of ideas is promoted. . . . . At present this sort of co-operation is loose, fragmentary, and disjointed; but an Exhibition brings the scattered experimentalists into systematic communication. Thus, both in the world of science proper and outside of it, a keener interest is likely to be cultivated in regard to scientific matters, and researches will consequently be conducted with greater spirit and efficiency, and better prospects of success. . . . . To persons of scientific training, or with even a rudimentary taste for such things, it is easy to conceive what service such an Exhibition will render. They will read the Handbook, an admirable summary of the chief branches of scientific study by competent authorities, and examine the objects exhibited; and thus lay up a store of suggestive information as a supplement to or a foundation for private studies. But there will also be a large body of people who will chiefly bring away from the galleries an impression of their own stupendous ignorance in such matters. This in itself, however, will be a good thing, for it may be expected, in some cases at least, to stimulate a desire to know something, and after that to know more. Even the dullest and least imaginative minds can hardly fail to be touched by the sight of the instruments by which the old masters achieved their triumphs, or of their earliest works. . . . . On the other hand, this Exhibition displays in a striking manner the wealth and luxury of scientific apparatus at the present day."

After giving examples of the intimate connection which subsists between the progress of science and the improvement of its mechanism, the article concludes thus:—

"It is impossible here to go through such an Exhibition in detail, and we can only say that it reflects much credit on those with whom it has originated, and that it is to be hoped that it may not be a mere passing show, but may develop into some permanent organization."

The *Academy* of last Saturday has "a first or introductory notice" of some length on the collection.

"The Special Loan Collection of Scientific Apparatus," the *Academy* says, "which was honoured by a private visit from her Majesty on Saturday last, and thrown open to the public on Monday, is one of very great interest and value. The Lord President of the Council may well be congratulated on the success of the undertaking, and we must all feel grateful to him for having given us an exhibition in which, for once, purely commercial interests have been made to give way to the 'higher aim of disseminating as widely as possible a knowledge of the different methods of science.' The Exhibition is in many respects the most instructive and remarkable that has been held at South Kensington, and though it may not have any great effect on the advancement of science or on the industrial progress of this country, it cannot fail to awaken a very general interest in those methods of abstract scientific research of which the public know so little; and it will afford an opportunity, which may never occur again, of examining at leisure under the same roof the rude, simple instruments used by the pioneers of science, and the complex, delicate apparatus with which investigators of the present day have made their discoveries. We trust, too, that the Exhibition may give an impulse to the cause of scientific education in this country, and that it may lead to a better appreciation of the reasons which have led men of science to advocate Government endowment of scientific research, and the establishment of Physical Observatories, at home and abroad, which may have the same beneficial influence on the progress of other sciences that Astronomical Observatories have had on the progress of astronomy. May we hope, too, that the Exhibition will lead to the creation of a museum for the illustration of physical, chemical, and mechanical sciences somewhat of the nature of the 'Conservatoire des Arts et Métiers,' in Paris? The formation of such a museum was one of the recommendations of the Commission on Scientific Instruction, and we believe it would go far, by affording adequate opportunities for study, to render the sciences alluded to as popular as those of botany, geology, and zoology."

Last week we quoted the opinion of *Iron*; the same paper has another interesting article this week, on "Science at South Kensington," in which it says that the success of the Exhibition affords an additional instance of the certain, if tardy, fructification of a valuable idea. "Years ago the conception of a great focus of science somewhere in the metropolis was formed in at least one great mind." The article then refers to the original intention of making the Albert Hall an institutional memorial, its employment as a place of scientific meetings and conferences having been strongly advocated. With its present uses, "the building has lost all its signification, as its position at South Kensington has lost all its appropriateness. We therefore cordially welcome the realisation of the spiritual part of the original plan, although it has been brought about by indirect means." The article then goes on to refer to the successful development of loan collections during the last few years, and the superior educational value possessed by special collections over large international exhibitions. As carried out at South Kensington, this value is largely

owing to classification, "a point kept distinctly in view in arranging the Exhibition of Scientific Apparatus." The article then proceeds: -

"The problem of classification has been triumphantly solved. . . . . Success is absolute and complete.

"The institution of conferences during the Exhibition can hardly be regarded as other than a most valuable innovation, and precisely what was wanted--not to popularise the Exhibition, but to give it that life and movement without which the best institutions are apt to become stagnant, and be passed heedlessly by in an age of hurry and bustle. . . . There is no slackness at South Kensington, and conferences form an interesting and important part of the programme of the Scientific Exhibition which it is rumoured will probably prove the nucleus of a Scientific Museum analogous to the Conservatoire des Arts et Métiers at Paris. It would certainly be shortsighted policy to allow the splendid collection of objects now brought together for the first time in the world's history to be redistributed--scattered all over Europe, in odds and ends which teach little or nothing apart, but are of inestimable value when together. The want of a permanent national institution devoted to science can now be supplied in the least costly and most efficacious manner, that is to say, the vital part composed of the scientists and their instruments. As for the showy part -the outward and visible sign the Central Hall of Science, it will come in time. If Albert Hall, after having failed as a music-hall, fails also as a circus and as a skating-rink, the country may one day be able to buy it up cheap, and convert it to a legitimate use."

The *British Journal of Photography* says:—

"There is now open in the Exhibition Buildings, South Kensington, London, a large, varied, and most valuable collection of scientific apparatus and appliances. Its intrinsic value is great, its historical value much greater, but in its educational importance is to be found the chief value of this unique collection."

The *Gardeners' Chronicle* speaks thus:--

"The splendid collections of Scientific Apparatus now on view at South Kensington may not have any great interest or attraction for the general public, for whose taste the display is too technical and unintelligible. To the more thoughtful visitor, and especially to the student, the collection is rich in interest and suggestiveness. . . . The whole thing has been organised and got together so quietly that even among scientific men little or nothing was known about the proceedings till the last moment, and the extent and value of the collections has come upon them as a surprise."

Public opinion thus far, it will be seen, has nothing but admiration for the Loan Collection. The *Athenæum* is on the other side. We give its article without note or comment, as the collection can hold its own.

"The galleries containing the Loan Collection of Scientific Instruments are at length open to the public. Apparently no expenditure has been considered too great by those who have been engaged in bringing together in the course of a few weeks from every part of Europe all the relics of science that could be begged or borrowed from public institutions or private collections. Gentlemen have been sent on special missions from South Kensington, and their movements have been duly chronicled in Reuter's telegrams amongst the most important news from Italy and Germany. Where these gentlemen could not find time to go, ambassadors and their attachés have been pressed into the service of collecting. Special railway trains have, we are informed by our contemporary, NATURE, been built for the transit of instruments, and the result is a collection of brass, glass, and old iron relics, which has driven the daily press wild with enthusiasm.

"According to the ordinary law of chances, a certain proportion of these instruments will be returned to the places whence they came all the worse for their journey across Europe, and we feel inclined to inquire whether it is certain that the worker in science will be the wiser for having seen them. The old and celebrated instruments have been repeatedly described and figured, and the new instruments, if useful, a man engaged in scientific research knows better than he knows the way to South Kensington. As to the curiosity-loving public, it will surely not be pretended that it is worth while to form such a collection for its amusement, but if it be the duty of government to gratify the craving of idlers, let us by all means at once appoint a Barnum to be Minister of Science; he will know how to make such exhibitions as this, and the School of Art needlework, a commercial success. But, no doubt, real instruction is intended, and if so, let us stop and ask whether the present is the best and cheapest plan of obtaining our object. The 'general public,' so far as can be judged from the experience of the first few days, regards the whole affair with indifference.

"In order to afford the means for studying the history of a science there is needed a continuous series of objects that will illustrate the development of thought step by step; such a collection cannot be brought together in a few weeks. It needs the patient labour and study of a lifetime devoted to it; but in this exhibition, as in collections made by the *nouveaux riches*, the extremely old and extremely curious have been brought side by side with the complicated results of modern workmanship; and we find none of the connecting links, to gather which requires a man well versed in the history of his subject, and the labour of a lifetime. . . . In fact, the collection required the control of a hand familiar with the history of astronomy. Objects that would have illustrated the development of the telescope during the seventeenth and eighteenth centuries should have been sought after more diligently than relics connected with great and popular names with which every one is familiar.

"The general 'Handbook to the Exhibition,' which has been published, is a remarkably good shilling's worth of information, but, as might be expected, it contains treatises of very different merit. After some general considerations on instruments by Prof. Clerk Maxwell, which will possibly be above the heads of most of his readers, follow some interesting though rather general disquisitions on various subjects, which have evidently in most cases been written without reference to the instruments brought together. The names of Prof. Clerk Maxwell, Prof. Smith, Prof. Clifford, Mr. Spottiswoode, Prof. Tait, and others, will be a sufficient guarantee of the trustworthiness of the information given. The article on Astronomy is not equal to the others, and considering the opportunity that the author had of illustrating the history of his subject, it is particularly poor and superficial. The 'Handbook' in general will well repay more than a casual perusal."

We did not state that "special railway trains" had been built for the purpose referred to above.

THE *Challenger* is expected home daily, and arrangements are being made for the ship being welcomed on its arrival at Sheerness by the Royal Society and the foreign men of science now in this country.

THE visitation of the Royal Observatory is fixed for Saturday, June 3.

THE Anniversary Meeting of the Royal Geographical Society was held on Monday. The total number of ordinary Fellows on the list at the end of April was 3,125. Sir H. Rawlinson, the President, presented the Founder's Medal to Lieut. Cameron, and the Patron's Medal to Mr. Lowther for Mr. J. Forrest, the Australian explorer. The annual geographical medals offered by the Society to the chief public schools were presented to the

following successful competitors, viz. :—In physical geography, gold medal, John Wilkie, Liverpool College; bronze medal, Walter New, Dulwich College; and in political geography, gold medal, Thomas Knox, Haileybury College; bronze medal, W. M. H. Milner, Marlborough College. The President then delivered the annual address on the progress of geography, in the course of which he announced that he had received a communication from the Chancellor of the Exchequer that morning, that, considering the very great importance of the discoveries of Lieut. Cameron, her Majesty's Government had decided to share the expenses of the Expedition. A sum of 3,000*l.* will be handed over to the Royal Geographical Society on that account.

THERE is at present being erected in the Paris Observatory Gardens a house for the Bishofsheim transit instrument, which has been admirably constructed by Eichens. The house possesses many peculiarities, and was designed by M. Leverrier for the better insuring of equality of temperature. The roof can be removed on horizontal rails, and the walls are so perforated that there is a continual circulation of air in all parts. The frame of the house may be said to be pneumatic, as it has been constructed on a system analogous to that of the bones of birds. It is sure to work admirably.

THE Woodwardian Museum at Cambridge has this week received an important accession in the rich collection of fossils presented by the veteran geologist, Mr. J. W. Walton, of Bath. In many respects, this collection, little known and studied by palæontologists, corresponds for the Southern Jurassic rocks to that of Mr. Leckenby, already at Cambridge, for the contemporaneous Yorkshire beds; but in addition, the general series of fossils is very interesting. Mr. Walton's Cambrian fossils constitute one of the finest existing assemblages from these rocks. Mr. Keeping, who has superintended the transfer to Cambridge, estimates the number of specimens at a hundred thousand; the entire weight is nearly two tons and a half. Thus the opportunities for palæontological investigation, at Cambridge already very great, are largely increased.

BIOLOGICAL students at Cambridge, and many others, will regret the approaching departure of Dr. Martin, Fellow and Lecturer of Christ's College, who has accepted the Professorship of Natural History in the University of Baltimore. Dr. Martin has attained the highest honours both at London and at Cambridge in a wide range of subjects. He has been largely associated with biological instruction at University College, London, and at South Kensington, while his connection with Dr. Michael Foster in the development of biology at Cambridge has been of great value. His co-operation with Prof. Huxley in the production of the very successful "Course of Practical Instruction in Elementary Biology," is well known. Some compensation for Dr. Martin's loss at Cambridge may be found in the thought that biology in the United States will gain by the presence of a man so well versed in European methods, and especially in the systems of instruction worked out by Prof. Huxley, Dr. Foster, and others in England.

FROM the daily Weather Maps issued from Hamburg by the German Seewarte, which embrace the whole of Europe, except the extreme south and the extreme north, we observe a very remarkable distribution of the atmospheric pressure for some weeks back. Barometers have been constantly low in southern or eastern regions, and high in the west and north, resulting in a persistent prevalence of northerly and easterly winds over nearly the whole of the continent. The maps suggest that this state of things has probably extended far to north-westwards, and in accordance with this supposition letters from Iceland inform us that the Greenland and Spitzbergen ice descended, in the beginning of this month, on the north coast of that island to a very serious extent, filling the sea as far as the eye could reach. In this connection, the observations made by the Arctic Expedition will have a peculiar meteorological value.

M. HOUZEAU has been appointed Director of the Royal Observatory of Brussels.

THE results of the daily photographs taken by M. Janssen at his observatory at Montmartre are rather interesting. In February a number of spots were visible and photographed; this number was gradually reduced to two groups, each consisting of two large spots, which were visible on March 13. By March 18 only two spots were visible, the two others having disappeared owing to the rotation of the sun. The two last disappeared by March 25, and from that time up to May 20 not a single spot was recorded, the solar disc appearing quite homogeneous. Such a phenomenon is very rare, indeed, although we are nearing the minimum. The photographs taken by Janssen are 20 centimetres diameter on a collodion film, when the sky is clear. Under unfavourable circumstances, the diameter is reduced to 10 centimetres. M. Janssen takes his photographs irrespective of the presence of clouds. He uses his celebrated *revolver*, and operates before ten o'clock in the morning. He is using not only the instruments taken to Japan for the last Transit, but the very canvas, with the canvas rotating domes. No doubt the Minister for Public Instruction will give him very shortly the means of building a permanent observatory, which is to be styled the Paris Physical Observatory. M. Janssen is also asking the means to build a large refractor worth 200,000 francs.

THE *Nord-Deutsche Allgemeine Zeitung* states that the German Imperial Government proposes to establish a Meteorological Institution, the meteorological department being up to the present moment merely a part of the statistical office.

AT a recent meeting of the Birmingham Natural History Society, the meteorite which recently fell in Shropshire, and to which we referred at the time, was exhibited and described. The following resolution was very properly passed unanimously by the Society:—"That in the opinion of this meeting the meteorite exhibited should become the property of the nation, in order that it may be submitted to the fullest scientific investigation at the hands of the most competent authorities." The above resolution was passed in consequence of an application made to the finder of the meteorite on behalf of the Duke of Cleveland.

L'Exploration of May 18 contains an account of the principal indigenous tribes of Eastern Siberia, taken from a recently-published work of M. Octave Sachot, "La Sibérie Orientale et l'Amérique Russe. Le Pôle Nord et ses Habitants." The information contained in the work seems to be mainly derived from the voluminous notes of an American engineer who sojourned for three years in the region in question.

M. TH. MOUREAU, an assistant in the Meteorological Service at the Paris Observatory, has been promoted, at the request of M. Leverrier, to the position of "Physicien adjoint," by M. Waddington. Although a young man, he has rendered important service in the provisional department of practical meteorology.

MR. A. SUTHERLAND, writing from Invergordon, Ross-shire, May 13, states:—For the last fortnight almost daily iridescent halos, of more or less completeness, have been noticed round the sun, towards evening. Those on the 5th and 10th were very brilliant. The former consisted of a rainbow-coloured circle reaching almost from the zenith to the horizon, and continued for two hours. The halo visible on the 10th was an almost complete example of the phenomenon, consisting of, when observed at 6.30 P.M., two iridescent circles (22° and 46°) with tangent arc and mock-suns. The inner circle of 22° showed more especially the red rays on its concavity, except at the parhelia, where it was

brightly iridescent. A pale light stretched through the sun from one parhelion to the other, and somewhat beyond these. The tangent arc of this inner circle was also very bright and well defined. The larger circle was complete except where the hills on the horizon hid a small portion. The tangent arc was not observed above it, the sky being clear where it would be projected. The day had been very warm, but towards evening a cold north-easterly wind blew, and the part of the sky where the sun was had become somewhat misty before the appearance of the halo. Lately the north-easter has plentifully furnished the conditions for the "icy cloud" which makes these appearances possible.

THE *Pandora* is expected to leave Portsmouth to-day for her Arctic cruise.

PROF. O. C. MARSH, in a short paper on some characters of the genus *Coryphodon*, Owen, figures the skull of the American *Bathmodon* of Cope, which he shows to be undistinguishable from *Coryphodon*. This oldest known representative of the ungulate animals, found in the London clay of England, the *Argile plastique* of France, and the lower Eocene of Utah, Wyoming, and New Mexico, possessed, besides the full complement of teeth (44), five digits on each limb, and a third trochanter to the femur. The cerebellum was peculiarly small, and the cerebrum very large in proportion.

THE Prefect of the Seine has appointed a Commission composed of M. Alphaud, the chief engineer of the city, two other engineers, and the head of the Public Gardens to study some of the public works of London, such as the Metropolitan Railway, the gardening of the public parks, the sewage and water system, &c. The French Minister of Public Works will be represented in that Commission by M. de Villiers, chief engineer of Ponts-et-Chaussées.

A COMMISSION has been appointed by the Prefect of the Seine to construct a number of primary clocks in Paris for the purpose of distributing the time by means of electricity. Up to the present time clockmakers have been obliged to make personal application at the Observatory to compare their chronometer with the standard chronometer, which is regulated by the observation of the celestial bodies once a week.

THE numbers of the *American Naturalist* for February and March contain, among other papers, one by Mr. A. Agassiz on Haeckel's Gastræal theory, one by Mr. H. D. Minot on the Summer Birds of the White Mountain Region, one by Dr. H. A. Hagan on the Development of Museums, one by Dr. J. G. Cooper on Californian Garden-Birds. There is also a reply by Dr. E. Coues to Mr. J. A. Allen's "Availability of certain Bartranian names in Ornithology." Dr. H. A. Hagan describes the Goshawk from among the Game Falcons of New England. Mr. Scudder describes the nature of the chirp of the Mole Cricket. Mr. Abbot writes on the indications of the antiquity of the Indians of North America, derived from a study of their relics.

WE observe from the recent numbers of the *Bulletin International* of the Paris Observatory that the annual reports for 1875 are being received, and in considerable numbers, from the presidents of the departmental meteorological commissions, as was earnestly requested some time ago by M. Leverrier, in order that the *Atlas Météorologique* for 1875, may appear with as little delay as possible. In proof of the activity and earnestness manifested by many of the departments, it may be stated that from the department of Bouches du Rhône tables of observations from thirty-one stations have been received—a number far from being too large if the meteorology of this part of France is to be prosecuted at all successfully with a view to its practical applications.

IN the same journal, of May 5, appears an interesting account by M. Piche, Secretary of the Meteorological Commission of the Basses-Pyrénées, of a sirocco which occurred in that department on September 1, 1874. On that occasion the shade-temperature near St. Jean-de-Luz rose from 78°·8 at 8 A.M. successively to 89°·6, 93°·2, 96°·8, and 101°·3. At Biarritz the temperature also rose to 101°·3, and the difference between the dry and wet bulbs at 4 P.M. amounted to 20°·7. The observations made at the nine meteorological stations of the department at the time, are given, but the number of stations is evidently too few to furnish the materials required for the investigation of this remarkable sirocco. An interesting point, however, is this—the almost unprecedented heat and drought at Biarritz occurred during a rapid and short-continued fall of the barometer, the heat and drought being at the maximum a little before the barometer fell to the lowest point.

WE have received *Osservazioni Meteorologiche*, anno v., No. 14, published under the direction of the well-known meteorologists, P. F. Denza and P. Maggi, by the Alpine Club of Italy. This number gives a full and detailed statement of the meteorological means and extremes during the second decade of April, 1876, at fifty-one stations situated on or in the immediate neighbourhood of the Alps and Apennines, the stations being at heights varying from 87 to 8,360 feet above the sea. The publication worthily occupies a well-marked sphere of operation, and its appearance thrice a month offers great facilities for the study of the meteorological changes in the course of the year along the slopes of these mountain ranges. It would much enhance the usefulness of the results if the barometric and thermometric means for 9 A.M. and 3 P.M. were given separately.

IN the *Fenland and Eastern Counties Meteorological Circular and Weather Report* for May there appear, in addition to the usual matter, the first of a series of papers by the Rev. W. Clement Ley, on wind laws, and a second notice of Mr. Buchan and Dr. Mitchell's paper on the weather and mortality of London, in which the author, Dr. J. M. Wilson, makes some interesting comparisons as regards a few of the most important diseases between the results obtained for London and those for Wisbeach.

AT a recent meeting of the Manchester Field Naturalists' and Archæologists' Society, Mr. Faraday gave an account of a plantation of the *Eucalyptus globulus*, at Hyères, in the department of Var, in the south of France. Three years ago M. Cortambert planted 2,000 seedlings a few inches high over one hectare of land. The trees are now about thirty feet high, the stems having a circumference of about fourteen inches at three feet from the ground. It has of course been necessary to thin the plantation. A branch in flower was recently laid on the table at a meeting of the French Central Society of Horticulture. The wood of the Eucalyptus is extensively used in Algeria for carriage building. Plantations of this tree are becoming numerous in the south of France.

THE full complement of sea-water required for the filling and successful maintenance of the marine tanks at the Westminster Aquarium—over 500,000 gallons—has been delivered, and the importation of marine specimens will be rapidly proceeded with. Many interesting examples of ocean life are already on view in the smaller tanks stationed in the Eastern Annexe.

THE additions to the Zoological Society's Gardens during the last week include a White-thighed Colobus (*Colobus bicolor*), from W. Africa, presented by Mr. A. J. Keason; a White-backed Trumpeter (*Psophia leucoptera*), from S. America, presented by Mr. H. S. Marks, A.R.A.; two Javan Fish Owls (*Ketupa javanica*), received in exchange; a Thar Goat (*Capra jemlaica*) born in the Gardens, the mother belonging to the collection of H.R.H. the Prince of Wales; a Falkland Island Thrush (*Turdus falklandicus*) from Chili, deposited.

SCIENTIFIC SERIALS.

American Journal of Science and Arts, April 1876.—Prof. Wright, of Yale College, examined last year the gases obtained at moderate temperature from a stony meteorite of Iowa County; their chief constituent was carbon dioxide. He has further examined several other meteorites of both classes (stony and iron, five of each), and the results, here communicated, confirm his former conclusions. Not only do the stony meteorites give off much more gas at low temperatures than the iron, but the composition is quite distinct. In no case of the latter was the amount of carbon dioxide more than 20 per cent. at 500°, nor than 15 per cent. from the whole quantity evolved, and the volume of carbonic oxide was, in every case but one, considerably larger. In the chondrites, on the other hand, the percentage of carbonic oxide is very small, while the carbon dioxide is (with one slight exception) more than half of the total quantity of gas obtained up to red heat. At a temperature of about 350° it constitutes from 80 to 90 per cent. of the gaseous products, in all cases, while at the heat of 100° it forms somewhat more than 95 per cent. in the two cases examined in this respect. The hydrogen, on the other hand, progressively increases in quantity with rise in the temperature of evolution, and in the last portions given off at a red heat is generally the most important constituent. The evolution of those large volumes of carbon dioxide may be taken as characteristic of the stony meteorites, and its relation to the theory of comets and their trains is certainly of great significance. Prof. Norton gives a succinct account of researches made with a view to determine the laws of the set of materials resulting from a transverse strain under various circumstances. He studied (1) sets from momentary strains, (2) sets from prolonged strains, and (3) duration of set, and variation of set with interval of time elapsed after the withdrawal of the stress. Some of the results are rather at variance, apparently, with the conception of the ultimate molecule, as made up of a limited number of precisely similar atoms endued with unvarying forces of attraction at certain distances and repulsion at other distances —According to Prof. Le Conte, mountain ranges are formed wholly by a yielding of the crust along certain lines of horizontal pressure; not, however, by bending of the crust into a convex arch filled and sustained by a liquid beneath, but by a crushing or mashing together horizontally of the whole crust with the formation of close folds and a thickening or swelling upward of the squeezed mass. In an interesting paper he adduces evidence of this from the coast range of California, which is destitute of granite axes, and has been little changed by metamorphism or overlaid by igneous ejections. Prof. Newcomb criticises somewhat unfavourably the physical theories of climate maintained in Croll's recent work on Climate and Time in their Geological Relations.—Prof. Mallet studies the constitutional formulæ of urea, uric acid, and their derivatives, and in an appendix Prof. Marsh describes the principal characters of the Brontotheridæ, with aid of some excellent plates.

Mind, April.—In this number Mr. G. H. Lewes draws attention to the absence of strictly defined technical terms in psychology, and "the deplorable and inevitable ambiguity" which in consequence clouds the discussion of psychological questions. After referring to various senses in which the words sensation, sensibility, consciousness are used, he puts the question: "are all changes in the sensitive organism to be included under the term consciousness, or only some changes?" We believe some psychologists would answer: no changes in an organism ought to be called consciousness.—Prof. W. Wundt of Leipsic contributes a solid paper on "Central Innervation and Consciousness." He accepts physical automatism as flowing from the doctrine of the conservation of energy. "If this principle lays claim to a universal validity, we cannot withdraw from it those movements which we are conscious of only as psychologically caused." What he means by psychological causation is not very clear.—M. Sidgwick's "Methods of Ethics" is ably reviewed by Prof. Bain, who while speaking of the work in terms of highest praise, finds, nevertheless, that justice has scarcely been done to utilitarian ethics, and when Mr. Sidgwick, finding no complete answer to the immoral paradox, "My performance of social duty is good not for me but for others," concludes that our cosmos of duty is in reality a chaos, Prof. Bain thinks that we have here "a sad ending to a great work;" and he proceeds to give a solution of his own, which some may consider little more than a restatement of the difficulty. The next paper is a criticism of Mr. Sidgwick's chapter on "Intuitionalism," by Mr. H. Calderwood, who endeavours to show that Mr. Sidgwick has "largely failed in the attempt to give a clear and fair representation of intuitionalism." The editor, Prof Croom Robertson, reviews Mr. Jevons's "Formal Logic." He praises the ability, ingenuity, and even success with which Mr. Jevons has laboured to construct a brand-new system, but is compelled at the same time to maintain the superiority of the methods of the traditional logic.—Mr. Shadworth H. Hodgson continues the work of distinguishing between philosophy and science. His present paper, "As Regards Psychology," is delightfully hard reading.—"Philosophy at Cambridge," is treated by Mr. H. Sidgwick.—A short kindly biography of James Hinton is written by Mr. J. F. Payne.—Critical notices, reports, correspondence, &c., make up the number.

Memorie della Società Spettroscopisti Italiani, November, 1875.—Prof. Bredichin writes an article on the spectra of certain nebulæ relating how he has adopted the plan of computing the lines of the spectrum of the nebula with the Fraunhoffer lines of the sun. The spectrum of a Geisler tube of hydrogen is used as an intermediate means of comparison. The mean positions of the lines are 5003·9, 5957·9, 4859·2 respectively. The first two lines agree very closely with the iron lines 5005·0 and [illegible]—A comparison of the solar diameters as obtained by the spectroscopic and transit methods by Secchi, Tacchini, and Rayet. The mean of the spectroscopic observations gave a diameter 1·8 less than the latter method.

December 1875.—Father Secchi contributes a note on his researches on the distribution of heat on the solar disc. Prof. Ricco writes on the perception and persistence of the sensation of colours. He throws a spectrum on a screen by reflection from an oscillating mirror, so that the spectrum is moved in a direction at right angles to its length backwards and forwards, and the shape of the apparent envelope of the coloured band shows that yellow is the most rapidly perceived colour, and the others decrease towards the red and blue.—Prof. Oudemanns writes on a method of heliometric measurement on the occasion of the transit of Venus.—Prof. Fergola writes on the dimensions of the earth, and researches on the position of the axis of figure with respect to the axis of rotation.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, May 18.—"Picrorocellin," by John Stenhouse, F.R.S., and Charles Edward Groves.

"On the Polarisation of Light by Crystals of Iodine," by Sir John Conroy, Bart., M.A. Communicated by A. G. Vernon Harcourt, Lee's Reader in Chemistry in the University of Oxford.

"Absorption-Spectra of Iodine," by Sir John Conroy, Bart., M.A. Communicated by A. G. Vernon Harcourt, Lee's Reader in Chemistry, University of Oxford.

Linnean Society, May 4.—Mr. G. Bentham, vice-president, in the chair.—Mr. G. Dawson Rowley and Mr. G. H. Parkes were elected Fellows of the Society.—Two foreign *savans* were chosen to fill the vacancies caused by death among the honorary members.—Mr. H. Trimen called attention to the photograph of a remarkable example of fasciated inflorescence occurring in *Fourcroya cubensis*, Haw. The specimen, coming under the observation of A. Ernst, of Caraccas, is recorded as 6½ feet high and 4 feet wide.—On behalf of Dr. Anderson there were shown specimens demonstrating the extraordinary diminutive eye of the Indian River Whale (*Platanista gangetica*), which animal to all intents and purposes must be well nigh blind; and likewise specimens of grasses (*Ischæmum rugosum* and *Paspalum scrobiculatum*) obtained from the stomach of the same creature, probably residual digesta of fish eaten by it.—Dr. Cobbold read a paper on Trematode parasites from gangetic dolphins. Three species were lucidly described, viz., *Distoma lancea*, *D. campula*, and *D. Andersoni*. The first of these was procured from the short-snouted Dolphin (*Orcella brevirostris*), a form more frequently captured in the Indian river estuaries. The last mentioned is entirely new to science. It and that immediately preceding (formerly designated *Campula oblonga*) were both obtained by Dr. J. Anderson from different specimens of the fluviatile Cetacean (*Platanista*). The special interest attached to the parasites in question may be thus summarised. 1. The circumstance of being obtained from Cetacean hosts not previously known to be

infested by them ... *D. lanca* and *D. campula* have each only once before (forty and twenty years respectively) been seen by any observer, and in either case from a different kind of whale. 3. The localities whence hosts and the Entozoa have been procured being situated regionally thousands of miles apart. 4. Verification of statements based on prior limited data. 5. The completion of our knowledge respecting the morphology and arrangement of all their more important internal organs. The author went on to generalise regarding the aberrance of host not producing departure of parasitic type, the relative periodic frequency and effects of such lowly organisms in wild and domestic animals, and the close alliance of the Plumaria to the forms treated. Mr. W. T. Thiselton Dyer read a paper on the genus *Hoodia*, with a diagnosis of a new species. He distinguishes three forms, viz., *H. Gordoni*, *H. Currori*, and *H. [illegible]*, and shows that in certain respects the genus *[illegible]* presents a close alliance. In the peculiarities of structure and recognition of parts of the floral envelope of *Hoodia* the author holds opinions diverging from those of Mr. Bentham, who previously had but a limited opportunity of examining this rare and interesting group of African plants. Mr. W. Duppa Crotch read a paper on the migration and habits of the Norwegian Lemming. Specimens belonging to him and Mr. A. [illegible] Alston illustrated certain moot points in the economy of these animals. The Rev. M. J. Berkeley communicated a report on the fungi collected in Kerguelen Island during the stay of the Transit of Venus Expedition of 1874-5. [illegible] the Cryptogamic flora of the island appears [illegible] represented in so far as number of species is concerned. A note on *[illegible]*, an oddly coloured kind of Marten inhabiting Cabul, by Dr. J. Anderson, was announced.

Geological Society, May 10.—Prof. P. Martin Duncan, F.R.S., president, in the chair.—W. [illegible], James [illegible], John William James, Mark Stirrup, and Charles Wilkinson were elected Fellows of the Society.—The following communications were read:—On some fossil reef-building corals from the Tertiary deposits of Tasmania, by Prof. P. Martin Duncan, F.R.S. The species described by the author were *[illegible]*, sp. n., *[illegible]*, sp. n., and a second species of *[illegible]*. Both these genera are composed of reef-building corals, and the species here described undoubtedly belonged to that category. They required the natural conditions peculiar to coral reefs. The author noticed the facts as to the distribution of land and water in the Australian region in Lower Cainozoic time which are revealed by the deposits belonging to that age, and indicated that although the insular distribution of the land may have been unfavourable to the growth of coral reefs, the existence of a suitable sea-temperature in the latitude of Tasmania is insufficiently explained. A single [illegible] of the old reef-building corals survives on the shores of Tasmania in the *[illegible]* [illegible], but all the other forms have died out. The coral isotherm would have to be 15° [illegible] south of its present position to enable reefs to flourish south of Cape Howe, and this could be caused only by a change in the arrangements of land and sea, and in the position of the polar axis. The author indicated the general arrangement of land which he seemed to have prevailed, and noticed that at that period and even earlier the coral isotherm of 74° reached fully 25° north of its present position in the portion of the globe antipodean to Tasmania, but it would seem to require more than mere geographical changes to account for the existence of important reefs in western, central, and southern Europe and in Tasmania synchronously. The flora underlying the marine Cainozoic deposits of Victoria indicate tropical conditions, as do the Echinodermata of the succeeding strata (described in the following paper). The fossil plants of the Arctic regions, from the Carboniferous to the Miocene epoch, give evidence of the existence of higher temperatures and of other conditions of light than those now prevailing, but were the polar axis at right angles to the plane of the ecliptic, and were there no greater node than at present, there would be equal day and night at all points. The difficulty is to account for the present position of the axis on this supposition, but the author suggested that the great subsidences of Miocene lands, the formation of the southern ocean, and the vast upheavals of northern areas at the close of the Miocene epoch, may have sufficed to produce the present condition of things.—On the Echinodermata of the Australian Cainozoic (Tertiary) deposits, by Prof. P. Martin Duncan, F.R.S. In this paper, after noticing the history of our knowledge of Australian Tertiary Echinida, the author gave a list of the species at present known, amounting in all to twenty-three, and described the following as new species:—*Leiocidaris australiae*, *Temnechinus lineatus*, *Arachnoides [illegible]*, *A. elongatus*, *Rhynchopygus dysasteroides*, *Echinobrissus australis*, *Holaster australis*, *Maretia anomala*, *Eupatagus rotundus*, and *E. [illegible]*. The author remarked upon the characters and synonymy of the previously known species, his most important statement being that the so-called genus *Hemipatagus* is in reality identical with the recent genus *Lovenia*, Gray, as clearly shown by fine specimens in his possession. The most marked genera of the existing Australian fauna are not represented, but are replaced by numerous Spatangoid ... three species, however, are identical, but two of these have a very wide range. Of the remainder, nine are allied to recent Australian species, mostly from the north of the continent; six are allied to European and Asiatic Cretaceous forms; five are closely related to Nummulitic types; and one species appears to belong to a peculiar genus, namely, *[illegible]*.—The Miocene fossils of Haiti, by Mr. R. J. Lechmere Guppy, F.G.S.

Anthropological Institute, May 9.—Col. A. Lane Fox, president, in the chair. In a paper with copious table, under the title of Prehistoric names of weapons, Mr. Hyde Clarke traced an early chapter in the history of culture showing that the names of weapons and tools were widely distributed among the aborigines of Africa, Asia, Australia, and America. He illustrated the archæological relation to the stone age by certain conformities between axe and knife and stone. In Africa, where some weapons [illegible] [illegible] as is known ... the evidence of names is strong in affirmation of its having passed through a stone epoch.—Canon Rawlinson read a paper on the ethnography of the Cimbri. There were two theories respecting them on this—the one that they were Germans, the other that they were Celts. The evidence on both sides was slight, and very nearly balanced. The majority of the early writers were in favour of the Celtic view. Cæsar, who pronounced the Cimbri to be German, may not have met with any of pure blood. Much would depend on the meaning of the term yellow hair and the reason for the employment of Celtic speech in the Cimbric camp. The name Cimbri has so near a resemblance to Cymry (the *b* in Cimbri being a usual Roman addition) that this was perhaps as good evidence as any in favour of the Celtic affinities of the race. On the whole Canon Rawlinson inclined to this view. A short communication from Prof. [illegible] describing the "Hunebedden," or stone monuments in Holland, was read by the Director, Mr. J. W. [illegible].

Entomological Society, May [illegible].—Sir Sidney Smith Saunders, C.M.Z.S., vice-president, in the chair.—M. Jules Lichtenstein, of Montpellier, was balloted for and elected a foreign member. The Rev. T. Hellins sent for exhibition various British Lepidoptera, recently submitted to M. Guenée for his opinion and determination. One of the most important was a *[illegible]*, bearing some resemblance to *[illegible]*, not known to M. Guenée, taken at Queenstown, flying over bramble blossoms, in July or August, 1872, by Mr. G. T. Mathew; it was also unknown, as European, to Dr. Staudinger.—Mr. Distant exhibited a series of six examples of the butterfly, *[illegible]*, Hewitson, from Costa Rica, showing a very considerable variation in markings to which the species is evidently liable. He also communicated some remarks on the *Rhopalocera* of Costa Rica, with descriptions of species not included in the Catalogue of Messrs. Butler and Druce, published in the "Proceedings of the Zoological Society" for 1874.—Mr. Douglas exhibited specimens of the Corozo Nut (*[illegible]*), the vegetable ivory of commerce, of which the interiors were entirely eaten away by a species of *Caryoborus* (one of the *Bruchidæ*). A specimen of the beetle was shown, with nuts, from the London Docks, which had been recently imported from Guayaquil.—The Secretary read a letter he had received from the Foreign Office Department, enclosing a dispatch from her Majesty's Minister at Madrid, relative to the steps taken to check the ravages of the locust in Spain. It appeared that considerable apprehension was felt in many parts of Spain that the crops of various kinds would suffer greatly this year from the locust, and the Cortes had already voted a large sum to enable the Government to take measures to prevent this calamity, and by a Circular addressed to the Provincial Governors by the Minister of "Fomento," published in the Official Gazette, they were directed to make use of the military forces stationed within their respective districts to aid the population in this object. It was stated that thirteen provinces were threatened with this plague.

Geologists' Association, April 7.—Mr. Wm. Carruthers, F.R.S., president, in the chair.—On the volcanoes of Iceland, with special reference to those mountains which have recently erupted, by W. L. Watts. The vast mass of the Vatna-Jokull rests upon a base of tuff and agglomerate traversed in many places by intruded basaltic and other lavas. This mountain and its immediate neighbours constitute the highest and probably the oldest part of Iceland, for its lava streams are in a state of ruin and decay unequalled in any other part of the country, and it is girt upon its southern base by sea-cliffs, which must have been washed by the ocean when many other parts of Iceland were under water, unless a very serious depression has taken place since the southern outlying hills of the Vatna and Skaptar Jokulls were washed by the sea. The fires in the Vatna are not yet extinct. Crossing the deserts to the north of the Vatna Jokull, on the west is a large tract of lava, the greater part of which has flowed from Skaldbreith, whilst in front rise the Dyngjufjoll or Chamber Mountains, the volcanoes which caused so much damage to the north of Iceland last spring. These mountains are composed of palagonitic agglomerate, and are in many places traversed by dykes and masses of lava, whilst numerous protruding scoriaceous crags suggest that lava streams may lie beneath. The sides have been fissured and cracked by the violent earthquakes which preceded the eruption of last spring. In the latitude of 65° 45′ N., and extending eastward towards the sea shore, the country was found to be strewn with a light vitreous pumice, very vesicular and assuming most beautiful shapes. The crater from which this was ejected is situated in the south corner of the Askja (oval wooden casket), the name given to an elevated piece of land enclosed upon all sides but the north-east by semi-detached sections of mountains. The fissures in this volcano were still in active eruption, sending forth vast volumes of steam, a dark granulated fetid earth which occasionally fell around in showers, and a little water. Copious floods of water had flowed down the sides of the volcano; this is the more remarkable, as the Dyngjufjolls are neither glacial nor snow-capped mountains. The Oskjagja (chasm of the oval wooden casket) is, moreover, at least thirty-eight geographical miles from the lake of Myvatn and forty-five from the nearest glacier. The second centre of recent volcanic activity is situated in the Myvatns Oræfi, where the volcanic fires first made their appearance last year. After the violent earthquakes which at Christmas, 1874, shook the north-east of Iceland, a fissure twelve miles in length, and varying from one to thirty feet in breadth, opened in the west portion of the Myvatns Oræfi, and commenced to eject lava from fourteen or fifteen different points. Many of the smaller fissures formed by these earthquakes cast up stones and ashes, and lava welled up through them. The great discharge of lava, however, was from the great fissure which formed a lava stream some thirteen miles in length, and varying from one to three in breadth; it has overflowed an older lava stream which had issued from a vent in the Myvatns Oræfi, called the Svinagja. This fissure broke out again in March, and continued in a state of intermittent activity until the following April. The lava is basaltic, and differs from the ancient streams only in its not containing olivine. The fundamental rock of Iceland is the palagonitic tuff of subaqueous origin, disturbed and at times metamorphosed by enormous masses of amygdaloidal basaltic lava; these are overlaid by subaerial lava streams, pumiceous tuffs, and agglomerates which have been formed by debacles and atmospheric influences. Trachytic lavas occur but sparingly, the trachytic band supposed to bisect the island from Cape Langaness to Reykjanes being unsupported by investigation. Trachytes in a much altered condition have been found around and between Hekla and the geysers. Obsidian is seldom met with *in situ*. Mount Paul, however, in the heart of the Vatna Jokull, consists of this rock, whilst the pumiceous outburst of the Oskjagja must also be referred to it.

May 5.—Prof. J. Morris, F.G.S., vice-president, in the chair.—On the section of the chloritic marl and upper greensand on the northern side of Swanage Bay, by H. George Fordham, F.G.S.—Notes on the geology of the neighbourhood of Swanage, by W. R. Brodie.

Institution of Civil Engineers, May 9.—Mr. W. H. Barlow, vice-president, in the chair. The first paper read was on the construction of railway wagons, with special reference to economy in dead weight, by W. R. Browne, Assoc. Inst. C.E.—"The second paper read was on railway rolling-stock capacity, in relation to the dead weight of vehicles," by Mr. W. A. Adams, Assoc. Inst. C.E.

CAMBRIDGE

Philosophical Society, Feb. 28.—The following communication was made to the Society by Prof. Clerk Maxwell, on Bow's method of drawing diagrams in graphical statics, with illustration from Peaucellier's cell. A frame is a structure consisting of pieces jointed together at their extremities. In diagrams the joints are represented by points, and the pieces by straight lines joining the points. A diagram of stress is a figure such that the forces acting at each joint of the frame are represented in direction and magnitude by the sides of a polygon in the diagram of stress. When the diagram of stress is such that to the lines which meet in a point in the diagram correspond the sides of a polygon in the frame, the frame and the diagram are said to be reciprocal. Mr. R. H. Bow, C.E., F.R.S.E., in his "Economics of Construction in relation to Framed Structures," has pointed out a method of constructing reciprocal diagrams which applies to cases which I had formerly thought impracticable. Mr. Bow assigns a letter to each enclosed space of the frame, and also to each division of the surrounding space as separated by the lines of action of the external forces. When two pieces of the frame cross each other without being jointed, Mr. Bow treats them as if they were jointed. The forces at the point of intersection are represented by a parallelogram. In the diagram of stress the letters are placed at the points which correspond to the enclosed spaces of the frame. In Peaucellier's cell the three external forces acting at the centre and the two bracing points meet in a point in the diagonal through the other two angles of the rhombus. To every positive cell in which the centre is outside the rhombus corresponds a negative cell in which the centre is inside the rhombus, and if the point of concourse of the forces is outside the rhombus in one case it is inside in the other. Every line in the one figure is parallel to the corresponding line in the other, and the only difference is that the acute angles of the rhombus in one figure correspond to the obtuse angles in the other. These two frames have the same diagram of stress, so that the stress of corresponding pieces in the two frames is the same.

March 13.—Mr. Lewis communicated a comment [illegible] distance taken by him under rather peculiar circumstances last autumn, Oct. 8.

March 27.—Mr. Ammison read a paper on the relation of the [illegible] to the [illegible] in mammals. On vital force, by Mr. H. F. Baxter.

MANCHESTER

Literary and Philosophical Society, Feb. 22.—Mr. E. Schunck, F.R.S., president, in the chair.—Notes on a collection of apparatus employed by Dr. Dalton in his researches, which is about to be exhibited (by the Council of the Literary and Philosophical Society of Manchester) at the Loan Exhibition of Scientific Apparatus at South Kensington, by Prof. Roscoe, F.R.S.—A letter from Mr. Arthur Wm. Waters, dated Naples, Feb. 9, 1876, was read by Mr. Baxendell, giving some account of the Naples Zoological Station.—On glacial action in the valley of the Wenn, &c., by Prof. F. S. Allis.

Feb. 29.—E. W. Binney, F.R.S., in the chair.—An account of some early experiments with ozone and remarks upon its electrical origin, by J. P. Dancer, F.R.A.S.—Results of rain-gauge observations made at Eccles, near Manchester, during the year 1875, by Thomas Mackereth, F.R.A.S.

March 7.—Mr. E. Schunck, F.R.S., president, in the chair.—Mr. R. S. Dale exhibited specimens of crystals of sulphate of lead found in alum [illegible].—On the degree of accuracy displayed by druggists in the dispensing of physicians' prescriptions in different towns throughout England and Scotland, by Mr. William Thomson, F.C.S.

March 13.—Prof. W. Boyd Dawkins, F.R.S., in the chair.—Mr. Charles Bailey exhibited a series of slides illustrating similarities of structure in Dicotyledonous and Monocotyledonous stems. Mr. R. D. Darbishire, F.G.S., exhibited a series of specimens of very young *Plaice* (*Platessa vulgaris*, Cuv.), showing, (1), the two eyes on each side of the vertical plane, (2), the removal of the eye from the under side to the dorsal edge, (3) the appearance of both eyes on the one (upper) side of the fish. He also communicated some notes made during a visit in the past summer to the Swedish shell beds of Uddevalla and the neighbouring district, and exhibited a collection of the fossils of remarkable extent and beauty. List of shells found in Cymmeran Bay, Anglesea. Corrections and additions, by Mr. John Plant, F.G.S. Addenda and corrigenda.

March 21.—Mr. E. Schunck, F.R.S., president, in the chair.

—Dr. Arthur Schuster exhibited an interesting collection of objects brought by him from Siam and the Western Himalayas. —On a graphical method of drawing spectra, by Mr. William Dodgson.—Evidence to prove that a bone from the Windy Knoll, Castleton, named by Prof. W. Boyd Dawkins, F.R.S., "Sacrum of young Bison," is a sacral bone of the Cave Bear (*Ursus spelæus*), by John Plant, F.G.S.

April 4.—Mr. E. Schunck, F.R.S., president, in the chair.—Prof. W. Boyd Dawkins, F.R.S., called the attention of the Society to the depreciation of silver which is now under the notice of a select committee of the House of Commons, and in connection with this called attention to the enormous mining wealth of the Nevada silver-mining district, a part of which he had had the opportunity of examining last autumn.—On some isomerides of alizarine, by Edward Schunck, F.R.S., and Dr. Hermann Roemer.—Prof. Boyd Dawkins, F.R.S., said with reference to the Windy Knoll bone, spoken of by Mr. Plant at the last meeting, that he had re-examined the evidence, and consulted Mr. Davis, of the British Museum, and found that he was mistaken in referring it to bison. The evidence of the jaws and teeth proves that the bear of Windy Knoll is not the cave, but the great fossil grizzly bear (*U. ferox fossilis* = *U. priscus*). as may be seen by a reference to the Quart. Geol. Journ., Lond., 1875, pp. 251-2.—The Eucalyptus near Rome, by Dr. R. Angus Smith, F.R.S., V.P.

April 18.—Annual General Meeting. — Mr. E. Schunck, F.R.S., president, in the chair.—The number on the roll on April 1, 1876, was 166.—Mr. Edward William Binney, F.R.S., F.G.S., was elected President.—Mr. W. E. A. Axon read a note on a church bell, at North Wooton, Somersetshire, dated A.D. 1265, in Arabic numerals, and on a MS. dated A.D. 1276, in which they are freely used.

VIENNA

Geological Society, March 7.—M. F. Karrer examined, together with M. Linzow from Odessa, the limestones and lime-sand beds of the environs of Odessa, and found that nearly the whole mass of them is composed of Foraminifers belonging to the genus Nubecularia, which attach themselves to various other bodies, and therefore appear in many different forms.—Director Ruecker stated the most recent results obtained concerning the division of the coal-strata of Ajka, in Hungary, and presented to the Society a rich collection of fossils from this country.—M. F. Posépny referred to the salt-pits of Bex, near Geuf, and argues that neither the salt-beds of the Alps nor those of other countries are bound to a fixed geological horizon.—Dr. R. Hornes on the remains of Anthracotherium [illegible] Zovencedo.

PARIS

Academy of Sciences, May 15.—Vice-Admiral Paris in the chair.—The following papers were read:—Meridian observations of small planets at the Greenwich and Marseilles Observatories during the first three months of 1876; communicated by M. Le Verrier.—Note on the theoretical and experimental determination of the relation of the two specific heats in perfect gases whose molecules are monatomic, by M. Yvon Villarceau. In the ideal case where each gaseous molecule consists of only one atom, the relation of the two specific heats would be independent of the chemical nature of the gas, and equal (the author showed) to 1·666. Now MM. Kundt and Warburg have lately obtained for mercury vapour the number 1·67. He suggests the possible existence of other monatomic gases. M. Berthelot reserved his assent to the conclusions regarding mercury vapour.—On a working model of a new system of navigation locks, applicable specially to cases where the surfaces of water of the canals are very variable, by M. de Caligny.—Second note on the bitter lakes of the Isthmus of Suez, by M. de Lesseps. Notwithstanding the solution of the bank of salt in the middle, and the evaporation, the saltness diminishes. This must be due to currents, produced through difference of density between the water of the lake and that of the extremities of the canal; the heavy water flows to the sea, while the surface currents bring in water that is less salt. Hence an orifice of small section may suffice to prevent large sheets of salt water, though far from the sea, being concentrated by the heat.—Study of several questions relative to the Suez Canal, M. de Lesseps. *Inter alia*, rain now falls at least twice a month; during the construction of the canal, previously to 1870, M. de Lesseps observed rain not more than once in the year.—On the danger of introduction of certain American vines into the vineyards of Europe, by M. Marès. This is on account of the phylloxera found in galls on the leaves of American vines.—Mineralogical and geological researches on the lavas of the dykes of Thera, by M. Fouqué. This memoir furnishes new data on the distinction of felspathic species, the simultaneous presence of several triclinic felspars in one rock, the structure of lava at the moment of effusion, and the bedding and production of tridymite in volcanic rocks.—On the phylloxera issue of the winter egg, by M. Boiteau. —Another note on the subject, by M. Lichtenstein.—On the presence of phylloxera in submerged vines, by M. Trouchaud.—On the effects produced by absence of cultivation at the surface of the soil, in vineyards attacked by Phylloxera, by M. François.—Ephemerides of the planet 162, by M. Rayet.—On determination of the temperature of solidification of liquids, and particularly of sulphur, by M. Gernez. The point of solidification is sometimes substituted for the point of fusion, being supposed identical with it; but the determination may be vitiated by phenomena of superfusion. M. Gernez utilises these phenomena to determine the temperature of solidification with great precision. He shows how the temperature of solidification varies in the different kinds of sulphur; only insoluble sulphur being constantly solidified at one temperature, 114°·3, whatever the temperature at which it has been fused.—On calorific spectra, by M. Aymonnet. He used a Bourbouze lamp, and a refracting system of flint. The heat maximum approaches the less refrangible part of the spectrum in proportion as the temperature of the source decreases. Flint becomes less diathermanous as the temperature falls; a solution of iodine in chloroform, more diathermanous. (The distribution of heat in the spectrum is indicated by numbers.)—On the presence of selenium in refined silver, by M. Debray. It is nearly always present, and comes from the sulphuric acid used in refining.—Chemical researches on vegetation (continued). Functions of leaves. Origin of carbon, by M. Corenwinder. Not only can leaves acquire carbon by their surface, but they can assimilate the carbon contained in the carbonic acid which circulates in their tissues.—On the heart of Crustacea, by M. Dogiel. The muscular bundles of the pericardium act in the opposite direction to those of the heart itself (they are dilators). The blood of Crustacea is to be considered as lymph, and their heart a lymphatic heart; its movements depending on the action of the nervous system on the muscular elements.—The limbs of the aquatic Salamander, fully extirpated, are not regenerated; note by M. Philipeaux. The basilar bones must be completely removed.—On the signification of the filament of the stamen, by M. Clos. He thinks it the analogue, not of the petiole, but of the nervure or median portion of the petals.—On the crystalline system of several substances presenting optic anomalies; theory of crystalline groups; explanation of dimorphism, by M. Mallard.—On a new mineral from the Pyrenees, by M. Bertrand. This, called Friedelite, is a hydrated silicate of protoxide of manganese.—On the flora of the sandstone of Fontainebleau, by M. Contejean. -On the antiseptic properties of borax, by M. Bedoin.--On a new motor based on the elastic force of solid bodies, by M. Arnaudeau.

CONTENTS

THURSDAY, JUNE 1, 1876

SCIENTIFIC WORTHIES

VIII.—CHARLES WYVILLE THOMSON

CHARLES WYVILLE THOMSON was born at Bonsyde, a small property in Linlithgowshire, which had been long in his family, on the 5th of March, 1830. All his early associations were with Edinburgh; his father was a surgeon in the East India Company's service, and spent most of his life abroad, but his grandfather was a distinguished Edinburgh clergyman, and his great grandfather was "Principall Clerk of Chancellary" at the time of the rebellion of 1745.

Wyville Thomson got most of his schooling at Merchiston Castle Academy, at that time under the excellent management of Mr. Charles Chalmers, brother of the famous divine. He left school and began the medical course in Edinburgh University in the year 1845. After studying for three years he fell into somewhat delicate health from overwork, and while still scarcely more than a lad, in 1850, to gain a year's rest, he accepted the lectureship on botany in King's College, Aberdeen. In the following year he was appointed lecturer on the same subject at Marischal College and University, which University conferred on him the degree of LL.D. He at this time was an indefatigable worker among the lower forms of animal life, and published several papers on the Polyzoa and Sertularian zoophytes of Scotland. Even at this time some of his philosophical speculations as to the development of certain Medusoid forms attracted notice, though they appear to have been considered too daring by Johnston, of Berwick on Tweed, and Edward Forbes. What would these worthies say, if they were living now, about the study of Ontogenesis as it at present exists amongst us?

Towards the close of 1853 a vacancy arose in the Professorship of Natural History (Botany and Zoology) in the Queen's College, Cork, owing to the resignation of the Rev. W. Hincks, F.L.S., and on August 26 Wyville Thomson received the appointment. He had, however, hardly settled down to the duties of this professorship, when a vacancy occurred in the Professorship of Mineralogy and Geology in the Queen's College, Belfast, by the resignation of Fred. M'Coy, who had been elected to one of the professorships in the New University of Melbourne. Wyville Thomson applied to be transferred to the Belfast chair, and was appointed thereto in September 1854.

The next five years were years of busy work for him. He added to courses of lectures on Geology and Mineralogy, he laid the foundation and built up a good deal of the superstructure of the present excellent Museum of the Queen's College, Belfast. In addition to many papers on zoological subjects, published by him at this date, we may mention one on a genus of Trilobites, read before the London Geological Society, and on a new fossil Cirriped, published in the "Annals of Natural History."

The study of fossil forms without a good knowledge of existing forms is in itself most useless, and a palæontologist of this sort is after all little more than a cataloguer; such was not Wyville Thomson. At this time, one most interesting group of the Echinodermata—the Lily Stars—attracted his attention, and while investigating the immense assemblage of extinct forms belonging thereto, he determined to know all that could be known about the life history of the few living forms. True, the illustrious Vaughan Thompson had some thirty years previously discovered and described a British Pentacrinus, and had determined that it was but the young stage of our common Rosy Feather-star; but a great deal remained to be done ere the history of even this form was complete, and it was not until the close of 1864 that Wyville Thomson's researches were sufficiently advanced to enable him to lay them before the Royal Society. They have since been published in the volume of the Philosophical Transactions for 1865, and it is not too much to say that this memoir will ever be a witness of the author's acute and accurate powers of research. The illustrations are all from exquisitely finished sketches by the author, and show a most enviable power of drawing, an art almost indispensable to the naturalist. These investigations on the pentacrinoid stages of Comatula were but part of a series of observations on the genus Pentacrinus itself, and Wyville Thomson amassed a lot of material with the object of writing a memoir on the group.

About 1864 the son of the illustrious Michael Sars, Professor of Zoology in the University of Christiania, was one of the Acting Commissioners of Fisheries for Norway, and as such was engaged in a series of scientific investigations as to the fisheries of the Lofoten Islands situated on the north-west coast of Norway. One day, dredging in water about 300 feet deep, for the purpose of determining the condition of the sea-bed, he obtained a number of specimens of a strange Crinoid, which at once struck him as being an immature pentacrinoid stage of *Comatula Sarsii*, with which he was familiar.

Here it is but right to mention that almost up to this date, men of science seemed to have made up their minds that life did not and could not exist below a certain depth of the sea. There were, according to Edward Forbes, five zones of depth: 1st, the littoral zone, between low and high water marks; 2nd, the Laminarian zone, from low water to a depth of fifteen fathoms; 3rd, the Coralline zone, from the fifteen fathom line to a depth of fifty fathoms; and 4th, the zone of deep-sea corals, extending from the edge of the Coralline zone to an unknown lower limit. In this region, as we descend deeper and deeper, its inhabitants become more and more modified and fewer and fewer, indicating our approach towards an abyss where life is either extinguished or exhibits but a few sparks to mark its lingering presence." Though the very general belief entertained by naturalists was that the depths of the sea were destitute of life, yet from time to time remarkable specimens were wont to be brought up from very great depths, and the occurrences, some of which were known to Forbes, had the evident effect of making him, during the latter part of his life, write cautiously on the subject. The reader who would care to know all that is known as to the records of the existence of life up to 1865, will find a full account thereof in Wyville Thomson's "Depths of the Sea."

G. O. Sars lost no time in announcing to his father his interesting discovery, and, acting on Prof. Sars's advice, he

went on dredging at depths of from 700 to 800 feet, finding an abundance of animal life. In the meanwhile the elder Sars, knowing that Wyville Thomson was working on the subject, sent him word of his son's discovery, of the significance of which he was still in doubt, and invited him to Christiania to see the specimen. He went, and on going over the matter together they came to the conclusion that the new Lily Star seemed to be closely related to a genus called *Bourgueticrinus*, a well-known fossil, and was consequently a degraded form of the family Apiocrinidæ. This was a startling discovery; it seemed now almost certain that there had been found not only a living representative of a long lost group, but a form that might be regarded as having lived on from the great Chalk epoch even into ours. In the train of thought thus excited, we think we see the material for speculation, then a fixed determination to prove—is this speculation true? then the trial trip in the *Lightning*, the more extended survey in the *Porcupine*, and lastly, all the brilliant results of the most remarkable voyage of discovery ever made, in the *Challenger*. It is not right to anticipate, and in pursuing our sketch we must not forget to mention that in 1860 Dr. Dickie, who was then a colleague of Wyville Thomson's as Professor of Natural History in the Queen's College, Belfast, was appointed to the Chair of Botany at Aberdeen, and at first temporarily and afterwards permanently, Wyville Thomson lectured on zoology and botany, becoming thus in very deed Professor of Natural History in the Queen's College, Belfast.

Prof. Wyville Thomson was, however, something besides a mere enthusiastic biologist; he was not merely content with rapidly increasing the zoological treasures of the Queen's College Museum; he did more. By interesting himself not only in what concerned the working of the College, but even in the welfare of the town in which it was located, he soon gathered round him a host of intelligent and warm-hearted friends. In social life it was but an accident that would reveal the Biologist, and one witnessed only the general culture and the artistic taste of a well-bred man. On one occasion of great moment in the history of the Queen's University in Ireland, Wyville Thomson's influence was felt, as we believe, for good. In 1866 a Supplemental Charter was given by the then Government to the Queen's University to enable it to confer degrees on students who might come up from any College that might be recognised as such by the Senate of the Queen's University. It seems hard to believe that such a charter should have been granted, for it might have given to any large school a position of equality to the three Queen's Colleges, and so have practically destroyed all middle-class education in Ireland. Wyville Thomson saw that the interests of education were at stake, and with commendable promptness and immense energy he initiated the formation of a committee and the collection of a sum of several thousands of pounds to try the validity of the new Charter in a court of law. In this the committee were successful, for the Charter was rendered inoperative by an injunction granted in 1867, after long and protracted arguments, by the then Master of the Rolls in Ireland.

Wyville Thomson was vice-president of the jury on raw products at the Paris Exhibition in 1867; he took the lead in organising the very flourishing School of Art in Belfast under the Science and Art Department, and was the first chairman of the Board of Directors. He is a Conservative in politics, and a magistrate and Commissioner of Supply for the county of Linlithgow.

In 1868 Dr. Carpenter, at that time one of the vice-presidents of the Royal Society, paid Prof. Wyville Thomson a visit in order that they might work out together the structure and development of the Crinoids. As the friends discoursed about these Lily stars, Wyville Thomson told Carpenter of his own firm conviction that the land of promise for the naturalist, indeed the only remaining region where there were endless novelties of most extraordinary interest, was the bottom of the deep sea; here were treasures ready to the hand which had the means of gathering them, and he urged him to use his influence at head-quarters in London to induce the Admiralty to lend to science, for a time, some small vessel properly fitted with dredging gear and the other necessary scientific apparatus, so as to definitely settle all these weighty questions. The Admiralty gave their sanction to the use of a Government vessel for the investigation, and the surveying ship *Lightning* left Oban for a cruise in the North Atlantic Ocean in August, 1868, returning to Oban by the end of September. For an account of this cruise we must refer to the "Depths of the Sea." The results of the *Lightning* expedition were fairly satisfactory. It was shown beyond question that animal life was varied and abundant at depths in the ocean down to between 600 and 700 fathoms; and it had been determined that great masses of water at different temperatures were moving about, each in its particular course; and, further, it had been shown that many of the deep-sea forms of life were closely related to fossils of the Tertiary and Chalk periods.

In 1869 the Admiralty once again acceded to the request of the Royal Society, and assigned the surveying vessel *Porcupine* for a survey to extend from May to September, 1869. The 1869 survey divides itself into three sections; the first when the *Porcupine* surveyed off the west coast of Ireland, Mr. Gwyn Jeffreys being in scientific charge; the second in the Bay of Biscay, in charge of Wyville Thomson; and the third, in which the track of the *Lightning* was carefully worked over, and all previous observations were duly checked.

Once again, in 1870, the Admiralty placed the *Porcupine* at the disposal of the Royal Society, and it was arranged that the year's expedition should be divided as in 1869, info cruises. Mr. Gwyn Jeffreys was to undertake the scientific direction of the first cruise from Falmouth to Gibraltar, and Wyville Thomson and Dr. Carpenter were to relieve him at Gibraltar, and to superintend the survey of the Mediterranean. Unfortunately a severe attack of fever prevented Wyville Thomson from joining the *Porcupine* at Gibraltar, and Dr. Carpenter took charge of the scientific arrangements.

In 1869 Wyville Thomson was elected a Fellow of the Royal Society.

In 1870 Dr. Allman resigned the Professorship of Natural History in the University of Edinburgh. Wyville Thomson was a candidate for the vacant chair, and amid the hearty congratulations of all men of science he was elected, vacating the chair in the Queen's College, Belfast, to which Dr. Cunningham was appointed.

On the return of the *Porcupine* from her last cruise, so much interest was felt in the bearings of the new discoveries upon important biological, geological, and physical problems, that a representation was made to the Government by the Council of the Royal Society, urging the despatch of an expedition to investigate each of the great oceans, and to take an outline survey of that vast new field of research, the bottom of the sea. The proposition of the Royal Society met with great and general support, and the *Challenger* was fitted out as England never before fitted out a vessel for scientific research.

The University of Edinburgh having given their consent, Prof. Wyville Thomson accepted the post of Director of the Civilian Staff; for this post none could have been better qualified; through his energy was it that this question of what lived in the ocean depths came to be investigated at all; the practical experience he had now gained could not be better utilised, while the subjects to be worked out were all within his reach. Able as a biologist to hold a high position, he combined with this more than an ordinary knowledge of chemistry, mineralogy, and geology, a knowledge far more than enough to enable him to encourage and sympathise with the labours of his staff.

The *Challenger* has now returned to our shores, her mission worthily accomplished, her officers and crew in the best of health and spirits.

All England welcomes Prof. Wyville Thomson back again, and thanks him for his voluntary exile of three and a half years from home and wife and friends for Science sake; and while we congratulate him on having laid a new realm at our feet and on having given us new food for thought, may we express in addition the hope that he will not long delay to give to the world the narrative of a cruise novel in its conception, successful in its results, and destined to live long in story.

THE CRUELTY TO ANIMALS BILL

IT is important that those who understand the national importance of science, as well as those who know how completely the art of medicine depends upon physiology should agree upon a common defence, now that both are so seriously threatened by legislation.

We do not think that scientific investigators can fairly claim to be entirely free in their choice of methods, on account of the importance of their objects, the purity of their motives, or the respectability of their character. Claims to absolute immunity from the interference of the State were maintained on precisely the same grounds by Churchmen in the Middle Ages, and the result proved how dangerous it is for any class of men to seclude themselves from the healthy atmosphere of free criticism and from contact with the popular conscience. A much better plea might be found in the small number of physiologists in this country, and in the important fact that, after many months of agitation and invective, their enemies were not able to bring before the Royal Commission a single authentic instance of cruelty. Still, considering the strong popular feeling on the subject, there are probably few who will deny that some legislation is necessary, if only to save physiologists spending their whole time in writing newspaper articles and going on deputations to Ministers.

What scientific men have a right to demand is that any regulations made should interfere as little with their legitimate objects as is compatible with the purpose of legislation. No one except a few obscure fanatics pretend that it is never lawful to subject animals to pain, or even to death, for self-preservation forbids such a rule; and no one can maintain that it is right to bleed calves and swallow oysters alive, for luxury, to geld horses for convenience, and hunt hares to death for sport, and yet that it is wrong to give one animal a disease that we may learn how to prevent or cure the same disease in thousands, or to perform a well-considered experiment which will certainly increase our knowledge of the laws of our being, and, more or less probably, tend to the relief of human suffering.

It is, therefore, of great importance that none of the objects which justify experiments on animals should be sacrificed in the effort to save the rest. Teachers of physiology in large and well-equipped schools might be content with a registration Bill which would leave them unmolested and forbid all research to outsiders; physicians and surgeons might demand liberty to do anything they choose which has a direct and immediate bearing on the relief of human suffering, and this appeal to self-interest would probably always be successful; independent investigators might see, without complaint, the teaching of physiology reduced to a study of words and opinions, and the advance of medical knowledge brought to a standstill, so long as they were left in peace. But such short-sighted narrowness would bring its own punishment. The results of independent research can only be obtained by those who have themselves been trained in genuine workrooms and can only be properly criticised by a properly instructed audience. Teaching without any attempt at original observation soon becomes lifeless and inexact; and medicine is far less indebted to experiment for the knowledge of the effect of certain drugs or operations, than for the broad basis of demonstrated facts as to the functions of the healthy organism on which all rational attempts to remedy them when disturbed must depend.

The scientific objects, then, which must, if possible, be protected from the mischievous Bill now before Parliament are, first, freedom of original investigation by competent persons; secondly, freedom of teaching by necessary demonstrations; and thirdly, freedom of experiment with the definite aims of the practical physician.

The best method of securing these objects while preventing the stain of cruelty from debasing the fair fame of science, would probably be that indicated by the Report of the Royal Commission. Laboratories would then be licensed under the control of responsible persons. Special certificates would be granted to competent investigators who, from distance or other causes, were not able to make use of these laboratories. The advance of sound physiological knowledge as well as the direct prevention or cure of disease, would be recognised as a legitimate object of experimental inquiry. The general condition of the licence or certificate would be that every experiment on a living animal should be rendered free from pain by the skilled use of chloroform (or other anaesthetic better adapted to the animal), except when this would defeat the object of the inquiry, and happily these exceptions

need be very few. Lastly, inspectors might fairly be appointed to see that not only in the actual experiments, but in the feeding, housing, and general treatment of the laboratory animals there was neither parsimony nor carelessness. The licence would be given on suitable recommendation by the Home Secretary, with power of revoking it for abuse, subject to appeal, as suggested in the Royal Commissioners' Report.

Under such an Act physiologists might fairly be expected to make it a point of honour that its provisions were fully carried out in spirit as well as in letter. The framers of the present Bill, by their disregard of physiology as an independent science, to be taught like any other, do their best to render its progress impossible; while, by their absurdly minute limitations, they would make original research almost as impossible as efficient teaching, and deprive the art of medicine of its only safe foundation.

The efforts of all who care for the advance of human knowledge or the alleviation of human misery should be directed to bring the scope of the Government Bill back to that indicated by the Report of the Royal Commission.

THE SCIENCE OF LANGUAGE

Language and its Study. By Prof. Whitney; edited by Dr. R. Morris. (London: Trübner and Co., 1876.)

Leaves from a Word-Hunter's Note-book. By the Rev. A. S. Palmer. (London: Trübner and Co., 1876.)

The Aryan Origin of the Gaelic Race and Language. By the Very Rev. U. J. Bourke (London: Longmans, Green, and Co., 1875.)

THESE three books are very fairly characteristic of the present position of comparative philology. The first is a reprint of the first seven chapters of Prof. Whitney's well-known work on the science of language, and has been admirably edited by Dr. Morris with notes and introduction, with special reference to a scientific study of English. The second is just what it professes to be, extracts from a commonplace book on the etymology of various words, and it illustrates very well the influence exercised by a comparative treatment of language upon what used to be the pastime of literary *dilettanti*. Mr. Palmer's derivations have been traced with full regard to the scientific method, and besides being accompanied by a wealth of quotations, rest for the most part on a secure foundation. "The Aryan Origin of the Gaelic Race," again, is one of those books which a few years back would have teemed with the wildest vagaries; the author, it is plain, has little critical judgment, but a diligent study of works like those of Zeuss or Max Müller has kept him in the right path, and though he startles us now and then with such assertions as that the Aryan is "the primeval language of man," or that "there had been only seventeen letters in Greek at the earliest period," his views are in general just and sound. We may doubt whether his theory of the Pagan origin of the Round Towers will be widely accepted, and complain of his prolixity, but the book is a striking example of the extent to which a knowledge of Comparative Philology has spread, and the wholesome influence its principles have exerted.

When we consider that the science of language is a science of not more than fifty years' growth, as well as the vast amount of details that had to be collected and classified before its creation became possible, its present advanced condition must be a matter of surprise. No doubt there is still very much to be done; some of the main questions connected with the study of language still remain unsettled, and new questions are starting up that will have to be answered hereafter. It is even possible that fresh knowledge and investigation will modify some of the hypotheses which have been accepted as fundamental truths.

Thus it might have been thought that the first question to be settled would be whether the science is to be included among the physical or the historical sciences, and yet this is even now a matter of dispute. There is much to be said in favour of both views. If we look merely to the fact that it lays down the laws in accordance with which thought endeavours to express itself in speech, it must be regarded as a historical science; if on the other hand, we consider that thought can only be expressed in speech by the help of physiological machinery, we are bound to class it among the physical sciences. If we make phonology not only the beginning, but also the end of linguistic science, linguistic science will differ but little from physiology in aim as well as in method; but if we remember that the various sounds which it is the province of phonology to determine and classify do not become language until they embody a meaning, the science of language will have to be grouped among those other sciences which deal with the history of human development. The same difficulty meets us again in the case of geology, which traces the history of the earth, and if with Prof. Whitney we prefer to regard the science of language as a historical science, while we call geology a physical science, it is because the element of mind enters more largely into the one, and the element of matter into the other. The laws which govern matter remain always the same; those which govern thought and life are modified by a process of internal development.

The science of language, otherwise called glotology or linguistic science, should, strictly speaking, be distinguished from comparative philology. The latter, by comparing words and grammatical forms within separate groups of languages, and thereby ascertaining the nature of these several groups and the laws which govern their growth and formation, provides the materials for the science of language. This takes the results obtained by comparative philology in the various species and genera or families of speech, and with the help of the comparative method determines from them the laws of speech generally. Inasmuch as we have to compare phenomena belonging not only to the same period, but also to different periods in the history of language, that part of linguistic research which is not purely phonological has to assume a historical character, so that to discover the causes of the phenomena is to explain their origin and process of growth. Now the phenomena of language are words and sentences, phonetic utterances, that is, which are or have been significant.

Perhaps the most important result of the science of language has been the demonstration that even language, even those "winged words" over which men once fancied they had the most complete control, are as much subject

But we must not forget that the science of language is still a young science. Its followers are still engaged in laying its foundations and testing their strength. The problems that await solution are numerous and important. So far as our evidence goes at present, it tends to show that the languages of the world have sprung from an infinite number of separate sources, but it remains to be seen whether future discoveries will not reverse this conclusion. Then, again, there is the question of roots All comparative philologists admit that roots are the ultimate elements into which language can be decomposed, but it is still a question whether the roots discovered by the grammarian once formed a spoken language, or whether they are but grammatical figments which are the best representatives we can obtain of the early condition of speech. Equally disputed is the question whether the different classes of language—inflectional, agglutinative, polysynthetic, and isolating—are to be regarded as constituting separate streams of linguistic development from the first, or a single stream which has branched out into separate ones It is unquestionable that a large part of flection can be shown to have had an agglutinative origin, it is also unquestionable that the phenomena of isolation are to be met with in the inflectional languages, and the phenomena of flection in the isolating languages but it is asked whether this would have been possible if each class had not had a definite tendency to flection or isolation from its starting—a standard, that is, to which all foreign elements introduced into the language were made to conform Such are some of the questions which still remain to be answered, and if we are to judge from the rapid progress already made by the science of language, the answers will not be long in coming

A H SAYCE

OUR BOOK SHELF

Rudiments of Geology By Samuel Sharp, F S A, F G S Second Edition. (London Edward Stanford, 1876)

THE author of this little manual, which is designed for the use of schools and junior students, has evidently taken considerable pains to make his work fairly represent the existing state of geological knowledge He has moreover, succeeded in conveying in simple language an idea, not only of the conclusions attained, but of the processes of investigation and reasoning, followed by the geologist in his researches, and we regard the book as well adapted to introduce a beginner to the study of the science, and to prepare him for the profitable perusal of more extended treatises As compared with some of the similar introductory text books of the science, which have recently been published, Mr Sharp's manual labours under the disadvantage of being somewhat inadequately illustrated, for we find in it only a few diagrams and no figures of fossils This second edition, however, is certainly a considerable improvement upon the first, and the division of Physical Geology has received much more full and careful treatment, the extent of the additional matter being sufficient to increase the number of pages of the book from 126 to 204

South Australia its History, Resources, and Productions Edited by William Harcus Illustrated with photographs taken in the Colony Published by authority of the Government of South Australia (London Sampson Low and Co, 1876)

THE nature of this handsome volume may be learned from the fact that it has been prepared to accompany the specimens of South Australian products and industries sent to the Philadelphia Exhibition It contains a vast amount of the most useful information on nearly all matters connected with the colony, gives an excellent idea of its present condition, and is likely to be of great use to intending settlers. Mr Harcus, who edits the volume, writes also one half of it, treating of the social, political, and industrial aspects of the colony In a series of valuable appendices, Dr Schomburgk treats of the flora of South Australia, Mr Waterhouse of its fauna, Mr J B. Austen of mines and minerals, while Mr Josiah Boothby contributes a statistical sketch of the colony, and Mr Charles Todd treats of its observatory and meteorology There are two very useful maps, while the illustrations are nearly all good and interesting

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications*]

The Spelling of the Name "Papúa

I QUITE agree with Mr Whitmee's objections to English orthography of foreign words (see NATURE, vol xiv p 48), but in this case I intended to show at a glance to *non-linguistic* readers that the accent in the word Papua must be on the second syllable, and not on the first The Germans write Papua,' and pronounce Papua (as they pronounce Mantua,' "Padua, &c) This being wrong, and fancying that in England the same mistake is often made, I wrote "Papuon," which leaves no uncertainty in respect to pronunciation I confess that it would have been more convenient to retain 'Papua,' and remark in a note that the accent must be on the 'u In a linguistic work I should never have proposed 'Papuon," but it cannot be supposed that every reader of NATURE knows what Marsden pointed out in 1812 In German I write "Papúa, and perhaps the same mode would be the most convenient in English It is known that the French use Papou, the Dutch 'Papoea, the Malay Papuwah In these cases the pronunciation may not be questionable, as it is in German and English if written 'Papua

The most interesting point in Mr Whitmee's letter is no doubt the announcement of a comparative grammar and dictionary of all the principal Malayo-Polynesian dialects and those interested in these studies will certainly be anxious to receive such a valuable increase to their knowledge

Dresden, May 25 A B MEYER

New Zealand Prehistoric Skeleton

AMONG the "Notes in NATURE, vol xiii p 196, just come to hand you give an extract from the Order Paper of the Legislative Council of New Zealand concerning the remains of a supposed 'prehistoric man, regarding which a motion for an inquest was tabled by Mr Walter Mantell As you correctly report, this skeleton was excavated under my direction in the so called Moa-bone Point Cave, but it was not found in the lower beds containing Moa bones, but in a much more recent formation, and to which I assigned a comparatively modern date

You state that I hold strongly to the [illegible] of the deposit, but I [illegible] to conceive what ground you have for such an assertion and as I can only conclude that you received your information direct from New Zealand, I beg to forward you herewith for your perusal a copy of my paper reporting the excavation and my views thereupon

With regard to the motion itself, which was treated throughout the colony as a joke, it is sufficient to state that Mr Walter Mantell is the recognised jester of the Legislative Council, and that even science does not escape his attempted witticisms I may add that the Hon Dr Pollen, the Premier of the Colony, also treated the motion as a joke, and offered Mr Mantell the office of coroner for the proposed investigation

Although Mr W Mantell, F G S, stated, when speaking on his motion (see Hansard, 1875, p 548), that "*he relied on the fact that he was not a scientific man, and he did hope he would be able to go to his grave without* [illegible] *that disgrace* never-

theless, he is known to have his pet theories about the antiquity of the Moa, and is very impatient of any contradiction.

I have thought it right to offer this explanation in order to prevent your readers being misled on a subject of considerable scientific interest JULIUS VON HAAST

Canterbury Museum, Christchurch, N Z, March 14

Visibility of the Satellites of Uranus

THE question of the visibility of these satellites in telescopes of moderate dimensions has lately excited considerable attention, but it does not appear that the question can be settled by any amount of verbal discussion I take the liberty, therefore, to propose two test objects by means of which any one can, I think, satisfy himself whether he can see these satellites or not

1 The companion of Regulus, north, preceding, and distant about three minutes of arc, has itself a small companion, which was discovered by the late Prof Winlock Any one who can see this small companion may be certain that he can observe the two outer satellites of Uranus and the satellite of Neptune

2 The star of fifth magnitude, A Leonis, has a companion discovered at the Naval Observatory by Mr G Anderson Any one who can observe this companion can, I think, see the two inner satellites of Uranus when at their elongations

Of course in the case of such faint objects very much depends on the condition of the atmosphere, but the above tests are very nearly correct. A AIH HALL

Washington, May 14

Protective Resemblance in the Sloths

IN a note upon the above subject, dated December 29 1875, which appeared in vol xiii p 187 of NATURE, I omitted to quote a passage from a letter written by Dr Berthold Seemann to the late Dr J E Gray (dated April 1, 1871), with regard to a specimen of *Arctopithecus*, of a well marked green colour, obtained by the former naturalist in Nicaragua Of this Sloth he says, *inter alia* — It should be born in mind that it has almost exactly the same greyish green colour as *Tillandsia usneoides*, the so-called 'vegetable horsehair' common in the district, and if it could be shown that it frequented trees covered with that plant (a point I hope to ascertain during my next visit in June next), there would be a curious case of mimicry between this Sloth's hair and the *Tillandsia*, and a good reason why so few of these sloths are seen' (Note on the species of *Bradypodida* in the British Museum, by Dr J F Gray, F R S, *Proc Zool Soc*, May 2, 1871) It would be interesting to know whether Dr Seemann succeeded in solving this question, I am, however, not aware of any further reference made by him to this subject

I here take the opportunity of correcting two misprints in my former letter, both of them in the Latin quotations, viz, "cum' for "cum, after the word "vellera,' in the first, and "coque" instead of "eoque' after the word "possint, near the end of the second passage J C. GALTON

OUR ASTRONOMICAL COLUMN

THE SECONDARY LIGHT OF VENUS During the next few weeks a very favourable opportunity will be afforded to observers in these latitudes for further examination of the planet Venus, with the view to a satisfactory solution of what must yet be regarded as a *questio vexata*— the visibility of that part of the disc, which is unilluminated by the sun, as the planet approaches or recedes from the inferior conjunction.

The subject is treated in detail in a communication to the Bohemian Academy of Sciences, from Prof. Safarik of Prague, entitled "Ueber die Sichtbarkeit der dunklen Halbkugel des Planeten Venus,' which appears in *Sitzungsberichte der Böhmischen Gesellschaft der Wissenschaften*, July 18, 1873 The author has collected together the many scattered observations extending over upwards of one hundred and fifty years, and presents also an outline of the various explanations which have been put forward

The earliest mention of the faint illumination of the dark side of Venus is by Derham, in a passage in his Astro-Theology, to which attention was first directed by Arago. Derham refers to the visibility of the obscure part of the globe "by the aid of a light of a somewhat dull and ruddy colour." The observation is not dated, but appears to have been prior to the year 1714 A friend of Derham's is also stated to have perceived the same illumination very distinctly

The next observations are by Christfried Kirch, second astronomer of the Berlin Academy of Sciences, June 7 1721, and March 8, 1726, and were found in his original papers and printed in *Ast Nach* No 1586 The image on the first occasion was tremulous, but though he could hardly credit his vision, he appeared to discern the dark side of the planet In 1726 he remarked that the dark periphery seemed to belong to a smaller circle than the illuminated one Kirch observed with telescopes of sixteen and twenty six feet focal length, powers 60 and 100 Two other persons confirmed his observation in 1726

The next observation in order of date, was found by Olbers, in "Observationes Veneris Grypiswaldensis", cited by Schroter in his observations of the great comet of 1807 It was made by Andreas Mayer Professor of Mathematics at Greifswald on October 20, 1759, observed the meridian passage of the planet, then at south declination of 21°, with a six foot transit instrument by Bird, power not much over 50, and has the remark— "Pars lucida Veneris tenuis admodum erat nihilominus integer discus apparuit, instar lunae crescentis qua acceptum a terra lumen reflectit ' As Prof Safarik justly observes considering the circumstances under which Mayer's observation was made with the planet only from the sun, and not more than 14 above the horizon the phenomenon on this occasion must have had a more unusual intensity

It does not appear that Sir W Herschel at any time perceived the secondary light of Venus, though he remarked the extension of the horns beyond a semicircle

Von Hahn, at Remplin, in Mecklenberg, the possessor of excellent telescopes by Dollond and Herschel, was fortunate in viewing the dark side of Venus on frequent occasions during the spring and summer of the year 1793 and he is considered by Safarik to have witnessed the illumination of this part of the disk under more varying conditions than any other observer The light is described as grey verging upon brown. Von Hahn's observations were made with various instruments and at different hours of the day

Schroter, at Lilienthal, on several occasions between the years 1784 and 1795, had remarked in full sunshine the extension of the horns of the crescent many degrees beyond the semicircle, the borders of the dark hemisphere being faintly illuminated with a dusky grey light, but on February 14, 1806 ... he saw for the first time the whole of the dark side as he expressed it, "in aussersт mattem dunkeln Lichte The sharply defined contour had an ash coloured light the surface was more dimly illuminated Schroter in recording this observation, expresses his surprise that during the many years he had observed the planet, part of the time with his 27 feet reflector, with the full aperture of 20 inches, he had not previously perceived the whole of the dark side, but he was satisfied there was no illusion At this time one eighth of the diameter of Venus, about 45', was fully illuminated, the planet cast a very sensible shadow

Harding, observing at Gottingen on January 24 of the same year, with a 10 feet Herschelian reflector, power 83 and full aperture of 9 inches, saw the whole dark side of Venus shining with a pale ash coloured light, very distinctly perceived against the dark ground of the sky The appearance was too evident to allow of the suspicion of an illusion, it was the same in all parts of the field of

view, and under various magnifying powers. Altogether the phenomenon was as distinct as in the case of our moon. On February 3, 16, and 21 it was not seen, but on the evening of February 28, it was again prominently visible to Harding; the illumination was now of a reddish grey, "like that of the moon in a total eclipse." Yet on the same evening Schröter looked in vain for the phenomenon at Lilienthal, showing how cautiously negative evidence should be received.

Observations of the secondary light were made by Pastorff in 1822 and by Gruithuisen in 1825.

The *Monthly Notices* of the Royal Astronomical Society contain many observations since the year 1842 by Messrs. Berry, Browning, Guthrie, Langdon, Noble, Prince, and others. Mr. Prince had favourable views of the illumination of the dark side in September 1863. Capt. Noble's observations, as remarked by Prof. Winnecke in his notice of Prof. Safarik's memoir, do not appear to refer to the secondary light as it has been perceived by other observers. He mentions that the hemisphere unilluminated by the sun has to him "always appeared distinctly and positively *darker* than the background upon which it was projected," a statement which certainly gives the observations a distinctive character.

There are also observations of the secondary light by Lyman, at Yale College in 1867, and about the same time by Safarik at Prague, and in August, 1871, more decidedly. In September of the latter year the whole disk of Venus was seen by Prof. Winnecke as described in *Ast. Nach.*, No. 1863. This astronomer has since stated that notwithstanding he has observed the planet many hundred times during the last twenty-four years, he has only succeeded in perceiving this remarkable illumination of the dark side on two occasions; and it should be added that Dawes, Madler, and other eminent observers, have never detected it. We shall revert to this subject next week.

THE OBSERVATORY AT ATHENS.—The death is announced of Baron Simon von Sina, son of the founder of the Observatory at Athens, which has been successively under the direction of M. Bouris and Herr Julius Schmidt. The deceased Baron is mentioned as a liberal patron of this establishment, though not himself engaged in scientific pursuits, and Herr Schmidt writes doubtfully of the future of the Observatory. Every astronomer will entertain the hope that this most laborious and successful observer distinguished not only by his great work upon the moon, but for his numerous discoveries and observations of variable stars, his long and important series of observations of comets, of short period and otherwise, in which he has made excellent use of the advantages of his southern position, and many other valuable contributions to observational astronomy—may continue to hold, under favourable auspices, the direction of an establishment which his exertions have made so honourably known in the astronomical world.

THE LOAN COLLECTION CONFERENCES

OWING to the pressure on our space this week, we can only refer briefly to what has been done since our last notice at the Conferences in connection with the Loan Collection. We give, however, in another part of the paper the presidential addresses of Dr. J. Burdon Sanderson, F.R.S., in the Section of Biology, and of Mr. John Evans, F.R.S., in the comprehensive Section of Physical Geography, Geology, &c. We hope in early numbers to be able to give at some length the principal papers which have been read in the various sections.

On Thursday last the concluding meeting in the Section of Mechanics was held, when the following papers were read:—"On Prime Movers," by Mr. Bramwell, F.R.S.; "The Construction of Furnaces," by Mr. Hackney; "A History of Electric Telegraphs," by Mr. Preece.

The first meeting in the Section of Biology was held on Friday, when the papers of which we gave a list in our last week's notice were read. This Section met also on Monday, when the following papers were read:—

Dr. Royston-Pigott, F.R.S., on a "Microscope with Complex Adjustments, Searcher, and Oblique Condenser Apparatus;" Prof. Rutherford, F.R.S., "On a Freezing Microtome;" Prof. Flower, F.R.S., "On the Osteological Preparations exhibited by the Royal College of Surgeons;" Herr Prof. Dr. Donders, "Ophthalmological Apparatus;" Dr. M'Kendrick, "Acoustical Instruments;" Prof. Yeo, M.D., and Dr. Urban Pritchard, "On Microtomes."

On Tuesday the first meeting in the Section of Physical Geography, Geology, Mineralogy, and Meteorology, was held, when, in addition to the President's Address, the following papers were read:—

Mr. R. H. Scott, F.R.S., "Meteorological Instruments in the Loan Collection;" Mr. G. J. Symons, "The Measurement of the Rainfall;" Dr. R. J. Mann, "Lightning Conductors;" M. le Professeur A. Daubrée, "La Géologie Synthétique;" Mr. J. E. H. Gordon gave an explanation of his Anemometer; Mr. C. O. F. Cator "On Anemometers;" Prof. von Oettingen gave a description of his Anemometer; Dr. R. J. Mann, "Lowne's Series of Anemometers;" Mr. John Evans, F.R.S., "Dalton's Percolation Gauge."

This Section meets again to-day and to-morrow, for which days the following programme has been drawn up:—For to-day.—Capt. Baron Ferdinand von Wrangell, "On Self-registering Tide-gauges;" Lieut. Cameron, R.N., "Physical Geography of South Tropical Africa;" Major Anderson, R.E., "Maps of Palestine;" Col. Walker, R.E., or Col. Montgomerie, R.E., "Discoveries in Tibet;" Mr. Francis Galton, F.R.S., "On Means of Combining Various Data in Maps and Diagrams;" Capt. Evans, R.N., C.B., F.R.S., Hydrographer of the Navy, "Hydrography, its present Aspects;" Capt. J. E. Davis, R.N., "The various forms of Sounding Apparatus used by Her Majesty's Ships in ascertaining the depth of the ocean, and the nature of its bottom;" Staff-Commander F. W. Creak, R.N., "Nautical Magnetic Surveys;" Prof. Roscoe, F.R.S., "Automatic Light Registering Apparatus." For to-morrow.—Prof. Ramsay, F.R.S., "The Origin and Progress of the Geological Survey of the British Isles, and the method on which it is conducted;" Mr. W. Topley, F.G.S., "The Sub-Wealden Boring;" Mr. C. E. de Rance, F.G.S., "Sketch of the Geology of the known Arctic Regions;" Mr. W. Galloway, "Colliery Explosions;" Prof. Baron von Ettingshausen, "The Tertiary Origin of the actual Flora;" Mr. J. S. Gardner, F.G.S., "The Tertiary Floras;" M. des Cloiseaux, Membre de l'Institut, "L'emploi des propriétés biréfringentes à la détermination des cristaux;" Mr. Walter Rowley, F.G.S., "Description of his Transit Theodolite for Mine Surveying, and other purposes;" The Rev. Nicholas Brady, M.A., "Desirability of a Uniform International Notation for Crystallography."

This will conclude these Conferences, which are admitted on all hands to have been a great success and to have added very much to the practical value of the collection. The popular expositions we referred to last week have been carried on with success, and apparatus may now be minutely inspected on Wednesdays, Thursdays, and Fridays, on application to the Director of the South Kensington Museum on forms provided for the purpose.

As we intimated last week, the Science and Art Department are organising a series of popular lectures in connection with the Loan Collection, to be given on the evenings of the free days—Mondays, Tuesdays, and Saturdays. We believe that the first of these lectures will be given on Saturday by Prof. Roscoe, F.R.S., on Dalton's Apparatus, and what he did with it."

THE CRUISE OF THE "CHALLENGER"

HER Majesty's ship *Challenger* was despatched towards the close of the year 1872, round the world, on a surveying and discovery expedition of a very special character. Her principal object as laid down in her instructions was to determine, as far as possible, the physical and biological conditions of the great ocean basins, the Atlantic, the Southern Sea, and the Pacific. The voyage was undertaken, as we have already said in our short biographical sketch of Prof. Wyville Thomson, chiefly in consequence of remarkable discoveries made during the four previous years, in short cruises, in H.M. gunboats *Lightning* and *Porcupine*, liberally detached by the Admiralty, at the instance of the Royal Society, for scientific research, under the direction of Dr. Carpenter, C.B., F.R.S., Mr. Gwyn Jeffreys, F.R.S., and Prof. Wyville Thomson, F.R.S. These discoveries seemed so important, not merely in a purely scientific point of view, but also in their bearings on ocean-telegraphy, that the Government determined to follow them up by a deep-sea survey on a more extended scale.

The *Challenger* was fitted out under the superintendence of Admiral Richards, C.B., F.R.S., at that time Hydrographer to the Navy, and in addition to a full naval surveying staff under the immediate superintendence of Capt. Nares, F.R.S., who was afterwards recalled to take command of the Arctic Expedition, a civilian staff of specialists in Natural Science and Chemistry was attached under the direction of Prof. Wyville Thomson.

The expedition, although by no means sensational, has been thoroughly successful. The *Challenger* has steadily traversed a track of 69,000 miles, and during her absence of three years and a half from England has established 362 observing stations, at all of which the depth has been ascertained with the greatest possible accuracy, and at nearly all the bottom temperature has been taken, a sample of the bottom water has been brought up for physical examination and chemical analysis, a sufficient specimen of the bottom has been procured, and the trawl or dredge has been lowered to ascertain the nature of the fauna. At most of these stations serial soundings have been taken with specially devised instruments to ascertain by the determinations of intermediate temperatures and by the analysis and physical examination of samples of water from intermediate depths, the directions and rate of movement of deep-sea currents.

The original arrangements for the cruise have worked in every way smoothly; the weather throughout has been on the whole favourable; under the careful management of Staff-Commander Tizard not a shadow of mishap has ever befallen the ship; there has been a perfect *bon accord* between the naval men and the civilians; all the appliances for carrying on the different operations, liberally supplied at first, were renewed by the officers of the Hydrographic Department of the Admiralty with the utmost liberality and precision.

Two events only have seriously affected the interests of the expedition, one, the sad death at sea of Dr. v. Willemoes-Suhm, one of the ablest of the naturalists on the civilian staff, the other the recall of Capt. Nares; for although Capt. Frank T. Thomson, who joined the *Challenger* from the *Modeste*, did everything in his power to fill his place, Capt. Nares, from his previous scientific training was so eminently fitted to lead such an expedition that his withdrawal in the middle of it was severely felt.

Leaving England on Saturday the 21st of December, 1872, some rough weather was encountered as the *Challenger* stood for the mouth of the Channel, and crossed the Bay of Biscay.

1873

On the 3rd of January, 1873, passing Cape Roca and the lovely heights of Cintra, she was quietly steaming up the Tagus, and came to anchor off Lisbon. Lisbon was left on the 12th. and a series of dredgings and examinations of bottom temperatures were made off Cape St. Vincent in from 400 to 1,200 fathoms. Gibraltar was reached on the 18th, and left on the 26th. The weather was now pretty moderate, and there was a very fairly successful week's sounding, trawling, dredging, and taking temperatures between the Rock and Madeira, which latter station was reached on the 3rd of February. Some of the dredgings made at this period appear to have been most successful, and a number of strange new forms of animal life were found, among these a fine new species of Venus's Flower-basket (*Euplectella suberea*), Fig. 1, a Bryozoon (*Naresia cyathus*), (see figure, vol. vii. p. 387) of singular beauty, which was dedicated to Capt. Nares, some wondrous forms of Sea-Urchins and Lily-Stars, and specimens of a species of "Clustered Sea-polype," since described by Dr. Kolliker under the name of *Umbellularia thomsoni*, an animal of great scientific interest.

But two days were spent at Madeira, and the *Challenger* was off Teneriffe early on the morning of the 7th, too early to attempt the ascent of the famous Peak, and rather too early for natural history work, still collections, both geological and zoological, were made, a series of dredgings were successfully tried between Teneriffe and Palma, past Gomera and Hierro, and a great number of observations as to temperature were taken. In the matter of meteorological observations we may mention that the officers of the Expedition seem to have excelled; the number of observations amounted during the first twelve months of the cruise to upwards of 50,000. Very considerable depths were found off the Canary Islands, extending sometimes to upwards of 1,700 fathoms; but the greatest depth found in this part of the Atlantic was one of 2,500 fathoms off Cape St. Vincent.

At Teneriffe the regular work of the Expedition may be said to have commenced. All the time between leaving home and arriving off the Canaries had been more or less devoted to getting the varied machinery into order, and in settling the direction and scope of the parts the members of the civilian staff had to play; so at Santa Cruz the old journals were closed, and the numbering of the stations and the other entries were commenced afresh, with some alterations the result of additional experience. A section was now to be carried right across the Atlantic from Teneriffe to Sombrero, the latter a little speck of an island north-west of Anguilla, and one of the group of Virgin Islands, themselves a portion of the West Indies. Sombrero was reached on the 15th of March, just a month from the time of leaving Santa Cruz. The distance between the two islands is about 2,700 miles, and along this line twenty-three stations were selected, at which most careful observations were made as to depth, condition, and temperature of bottom. During one of these dredgings, and at a depth of 1,500 fathoms, several specimens of a magnificent sponge belonging to the Hexactinellidæ were found attached to the branches of an Isis-like coral, and nestling among the fibres of the sponge were star-fishes, annelids, and Polyzoa. Often during this cruise, when the weather was calm and hot, the tow-net was used on the surface. It would seem that the greater number of the pelagic forms retire during the heat of the day to the depth of a few fathoms, and come up in the cool of the evening and in the morning, and in some cases in the night. The larger phosphorescent animals were frequently abundant during the night round the ship and in its wake, while none would be taken during the day One day (the 26th of February), the morning being bright and clear and the swell not heavy, the ship being some 1,600 miles from Sombrero, and in lat. 23° 23′ N., long. 32° 56′ W., the sounding-line indicated a depth of 3,150 fathoms, and the bottom was found to consist of a perfectly smooth red clay, containing scarcely a trace of organic matter. This was the greatest depth as yet met with, and the material from the bottom

was something quite novel to the explorers. At the mean maximum depth of some 2,200 fathoms the ooze was one vast mass of the calcareous shells of foraminifera, but as the soundings got deeper the ooze began to assume a darker tint, and showed, on analysis, a continually decreasing quantity of calcareous matter. Now in this red ooze almost no calcareous forms were to be met with, and it was of extreme fineness, remaining for a long time in suspension in water, and proving on analysis to be almost pure clay, a silicate of alumina and the sesquioxide of

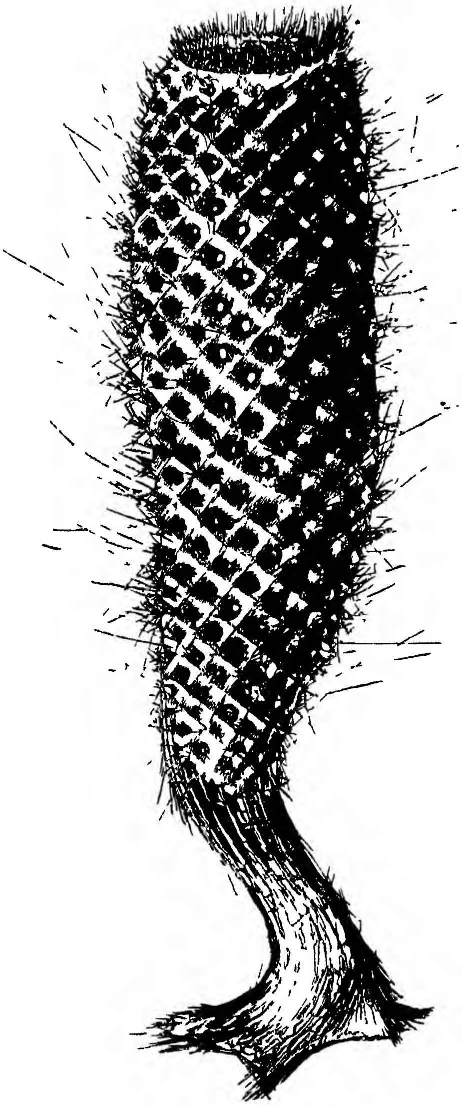

FIG. 1.—*Euplectella suberea.*

iron, with a small quantity of manganese; and at this depth there appeared to be an absence of animal life.

Prof. Wyville Thomson considers it as quite proved that all the materials for such deposits, with the exception of the remains of those animals which are now known to live at the bottom at almost all depths, are derived from the surface; and considering the very enormous extension of the calcareous ooze, it becomes important to know something of the minute foraminifera that produce it. In all seas, from the equator almost to the polar ice, the surface-water contains *Globigerinæ*. They are more abundant and of a larger size in warm seas; several varieties attaining a large size, and presenting marked varietal characters, are found in the intertropical area of the Atlantic. In the latitude of Kerguelen they are less numerous and smaller, while further south they are still more dwarfed, and only one variety, the typical *Globigerina bulloides*, is represented. The living *Globigerinæ* from the tow-net are singularly different in appearance from the dead shells we find at the bottom (Fig. 2). The shell is clear and transparent, and each of the pores which penetrate it is surrounded by a raised crest, the crest round adjacent pores coalescing into a roughly hexagonal network, so that the pore appears to lie at the bottom of a hexagonal pit. At each angle of this hexagon the crest gives off a delicate flexible calcareous spine, which is sometimes four or five times the diameter of the shell in length. The spines radiate symmetrically from the direction of the centre of each chamber of the cell, and the sheaves of long transparent needles, crossing one another in different directions, have a very beautiful effect. The smaller inner chambers of the shell are entirely filled with an orange-yellow granular sarcode; and the large terminal chamber usually contains only a small irregular mass, or two or three small masses run together, of the same yellow sarcode stuck against one side, the remainder of the chamber being empty. No definite arrangement, and no approach to structure, was observed in the sarcode; and no differentiation, with the exception of bright-yellow oil-globules, very much like those found in some of the Radiolarians, which are scattered apparently irregularly in the sarcode, and usually one very definite patch of a clearer appearance than the general mass coloured vividly with a carmine solution. The presence of scattered particles of bioplasm was indicated by minute spots here and there throughout the whole substance which received the dye.

When the living *Globigerina* is examined under very favourable circumstances, that is to say, when it can be at once placed under a tolerably high power of the microscope in fresh still sea-water, the sarcodic contents of the chambers may be seen to exude gradually through the pores of the shell, and spread out until they form a kind of flocculent fringe round the shell, filling up the spaces among the roots of the spines and rising up a little way along their length. This external coating of sarcode is rendered very visible by the oil-globules, which are oval, and filled with intensely-coloured secondary globules, and are drawn along by the sarcode, and may be seen, with a little care, following its spreading or contracting movements. At the same time an infinitely delicate sheath of sarcode containing minute transparent granules, but no oil granules, rises on each of the spines to its extremity, and may be seen creeping up one side and down the other of the spine with the peculiar *flowing* movement with which we are so familiar in the pseudopodia of *Gromia* and of the Radiolarians. If the cell in which the *Globigerina* is floating receive a sudden shock, or if a drop of some irritating fluid be added to the water, the whole mass of sarcode retreats into the shell with great rapidity, drawing the oil-globules along with it, and the outline of the surface of the shell and of the hair-like spines is left as sharp as before the exodus of the sarcode.

There is still a good deal of obscurity about the nature of *Orbulina universa*, an organism which occurs in some places in large proportion in the globigerina ooze. The shell of *Orbulina* (Fig. 3) is spherical, usually about ·5 mm. in diameter, but it is found of all smaller sizes. The texture of the mature shell resembles closely that of *Globigerina*, but it differs in some important particulars. The pores are markedly of two different sizes, the larger about four times the area of the smaller. The larger pores are the less numerous; they are scattered over the surface of the shell without any appearance of regularity; the smaller pores occupy the spaces between the larger. The

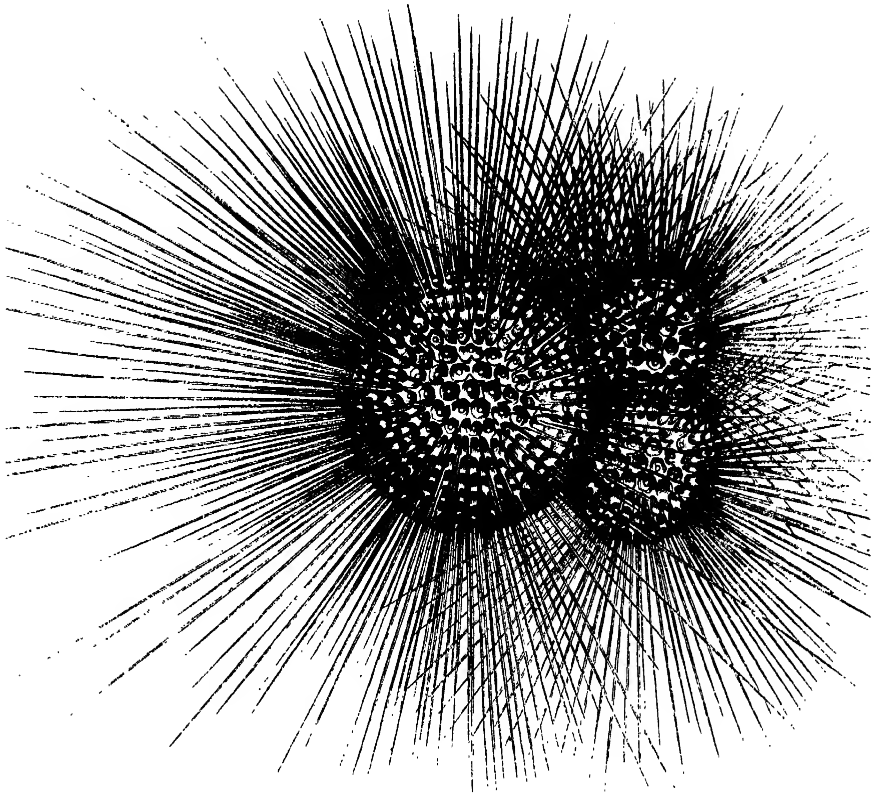

FIG. 2.—*Globigerina.*

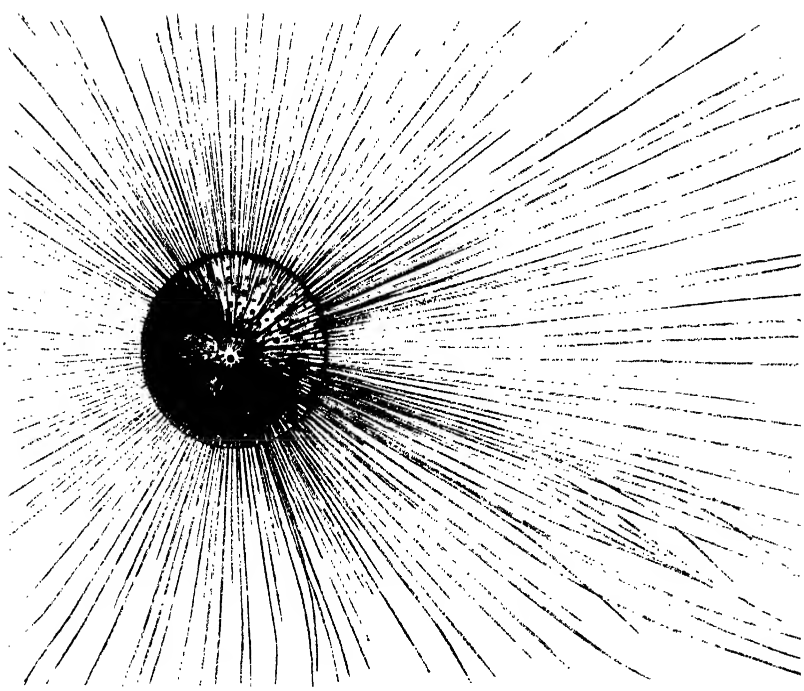

FIG. 3.—*Orbulina.*

crests between the pores are much less regular in *Orbulina* than they are in *Globigerina;* and the spines, which are of great length and extreme tenuity, seem rather to arise abruptly from the top of scattered papillæ than to mark the intersections of the crests. This origin of the spines from the papillæ can be well seen with a moderate power on the periphery of the sphere. The spines are hollow and flexible; they naturally radiate regularly from the direction of the centre of the sphere; but in specimens which have been placed under the microscope with the greatest care, they are usually entangled together in twisted bundles. They are so fragile that the weight of the shell itself, rolling about with the motion of the ship, is usually sufficient to break off the whole of the spines and leave only the papillæ projecting from the surface in the course of a few minutes. In some examples, either those in process of development, or a series showing a varietal divergence from the ordinary type, the shell is very thin and almost perfectly smooth, with neither papillæ nor spines, nor any visible structure except the two classes of pores, which are constant.

The Coccospheres and Rhabdospheres—these are suggested to be minute algæ forms—live on the surface, and sink to the bottom after death. Many of them are extremely beautiful, as will be seen from Figs. 4 and 5, representing two forms first discovered by Mr. Murray.

Taking the section from Teneriffe to Sombrero, first of all some 80 miles of volcanic mud and sand were passed; then some 350 miles of globigerina ooze; next about 1,050 miles of red clay; then again a rising ground for some 330 miles of globigerina ooze, a valley of 850 of red clay; and nearing land some 40 miles of the globigerina ooze. Intermediate between the red clay and the globigerina ooze, a grey ooze was met with, partaking of the characters of both, and evidently a transitional stage. "There seems to be no room," writes Prof. Wyville Thomson, "left for doubt that the red clay is essentially the insoluble residue, the *ash*, as it were, of the calcareous organisms which form the 'globigerina ooze,' after the calcareous matter has been by some means removed. An ordinary mixture of calcareous Foraminifera with the shells of Pteropods, forming a fair sample of 'globigerina ooze' from near St.

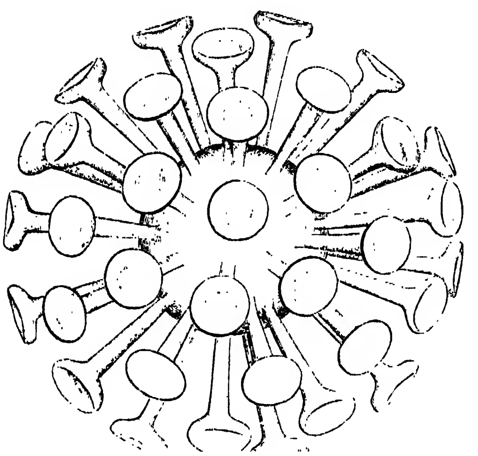

Fig. 4.—Rhabdosphere.

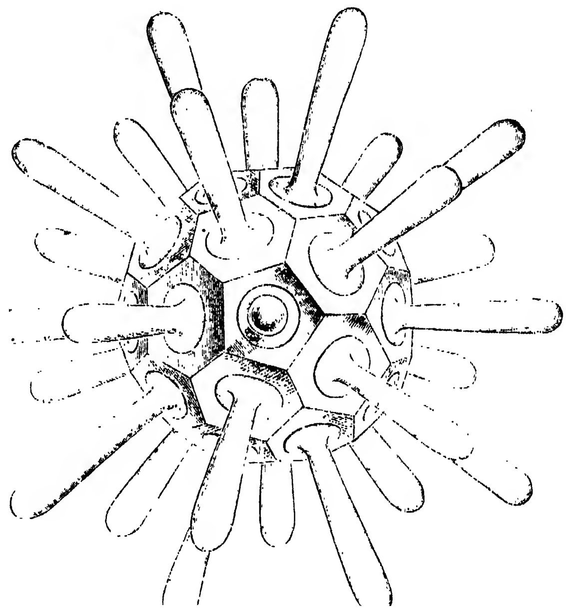

Thomas, was carefully washed and subjected by Mr. Buchanan to the action of weak acid; and he found that there remained, after the carbonate of lime had been removed, about one per cent. of a reddish mud, consisting of silica, alumina, and the red oxide of iron. This experiment has been frequently repeated with different samples of 'globigerina ooze,' and always with the result that a small proportion of a red sediment remains, which possesses all the characters of the 'red clay.' I do not for a moment contend that the material of the 'red clay' exists in the form of the silicate of alumina and the peroxide of iron in the shells of living Foraminifera and Pteropods, or in the hard parts of animals of other classes. That certain inorganic salts other than the salts of lime exist in all animal tissues, soft and hard in a certain proportion, is undoubted; and I hazard the speculation that during the decomposition of these tissues in contact with sea-water and the sundry matters which it holds in solution and suspension, these salts may pass into the more stable compound of which the 'red clay' is composed."

On this voyage Mr. Buchanan found the remarkable and unexpected result that the water has virtually the same specific gravity from the bottom to within 500 fathoms of the surface. From 500 fathoms the specific gravity rapidly rises till it usually attains its maximum at the surface. Nineteen dredgings were taken, and these yielded a large supply of animal forms. It is unfortunate that in the deepest haul of all, 3,150 fathoms, no living thing was brought up higher in the scale than a foraminifer; but this may be attributed to the nature of the bottom, an opinion borne out by the abundance, at scarcely a less depth, and on a bottom differing only in being somewhat less uniform, and containing sand-grains and a few shells of foraminifera, of tube building annelids of a very common shallow water type. The crustacea do not appear to suffer from the peculiarity of the circumstances under which they live, either in development or in colour. The singular fact of the suppression of the eyes in certain cases is already well known. The Echinoderms and sponges which enter so largely into the fauna of the zone ending at 1,000 fathoms are not abundant at extreme depths.

The *Challenger* next anchored off the harbour of Char-

lotte Amalia, at St. Thomas, where a pleasant week was spent, and on the 25th of March she proceeded on her way to the Bermudas. On Monday the 26th, being then in lat. 19° 41′ N., long. 65° 7′ W., and nearly ninety miles north of St. Thomas, a sounding was made in the great depth of 3,950 fathoms, and a dredge was let down to see if it would prove serviceable; heaving-in commenced at 1.30, and the dredge came up at 5 P.M. with a considerable quantity of reddish-grey ooze. No animals were detected except a few small foraminifera with calcareous tests, and some considerably larger of the arenaceous type.

On the 4th of April she made her way through the intricate and dangerous "narrows" between the coral reefs, and by the evening was at anchor at Grassy Bay, Bermudas. A fortnight was spent at these Islands. Their geological structure was most carefully studied, and when the narrative of the cruise is published we may expect very valuable information as to the formation of the various forms of limestone to be found on these islands. The principal islands are well wooded, but the great preponderance of the Bermudian Cedar (*Juniperus bermudiana*) gives a gloomy character to the woods, which in the annexed woodcut is somewhat relieved by the presence of some palm trees (Fig. 6). The Admiral's official residence, Clarence Hill, is situated on an inclosed little bay called Clarence Cove. The garden was rich with a luxuriant tropical vegetation of which the group of papau trees, *Carica papaya* (Fig. 7), will give some idea.

There is only one kind of rock in Bermudas. The islands consist from end to end of a white granular limestone, here and there becoming grey or slightly pink, usually soft and in some places friable, so that it can be broken down with the ferrule of an umbrella; but in some places, as on the shore at Hungry Bay, at Painter's Vale, and along the ridge between Harrington Sound and Castle Harbour, it is very hard and compact, almost crys-

FIG. 6.—Swamp Vegetation, Bermudas.

talline, and capable of taking a fair polish. This hard limestone is called on the islands the "base rock," and is supposed to be older than the softer varieties and to lie under them, which is certainly not always the case. It makes an excellent building stone, and is quarried in various places by the engineers for military works (Fig. 8). The softer limestones are more frequently used for ordinary buildings. The stone is cut out of the quarry in rectangular blocks by means of a peculiarly constructed saw, and the blocks, at first soft, harden rapidly, like some of the white limestones of the Paris basin, on being exposed to the air.

Immense masses of fine coral sand surround the shores, being washed in by the sea. It is then caught at certain exposed points by the prevailing winds, and blown into sand-hills often forty to fifty feet in height. Sometimes these sand-masses form regular sand-glaciers. One of these was found at Elbow Bay on the southern shore of the main island. The sand has entirely filled up a valley and is steadily progressing inland in a stream some five and twenty feet. It has, as will be seen in the woodcut (Fig. 9), partially overwhelmed a garden, and is still flowing slowly on. When the photograph from which the woodcut is copied was being taken, the owner of the garden was standing with his hands in his pockets, as is too much the habit of his race, contemplating the approach of the inexorable intruder. He had, as will be seen, made some attempt to stay its progress, by planting a line of oleanders and small cedars along the top of the slope, but this had been in vain.

The botanists of the expedition paid a good deal of attention to the flora of the island, and we may expect a lot of new forms among the minute algæ found in the so-called freshwater ponds or lakes.

Bermudas was left on the 20th of April, and a section was carried out from the islands towards Sandy Hook,

and then south and west of Little George Bank and into Halifax on the 9th of May. In this run several soundings were taken at depths of from 2,600 to 2,800 fathoms. The bottom yielded chiefly grey ooze, and the course of the Gulf Stream was crossed. Staying a week at Halifax to recruit, the next section was made in almost a straight line from Halifax to Bermudas, which was reached on the 30th of May, nine important stations having been selected and examined on the way. A short time was passed at Bermudas, and the next section it was determined to make was one between lat. 35° and 40° to the Azores. Leaving Bermudas on the 12th of June the *Challenger* was off Fayal on the 1st of July, having successfully made observations at seventeen stations *en route*. A small-pox epidemic having broken out at Fayal, it was not deemed prudent to land. San Miguel was visited, and the straits between it and Santa Maria were explored, and the *Challenger* on the 10th stood for Fauchal, reaching it on the 15th, having been now more than a month at sea. Having made two sections right across the Atlantic, all looked to enjoying a few days on land, but it was not to be so, for most unluckily a rather severe epidemic of small-pox had broken out at Madeira also shortly before, and Capt. Nares did not think it prudent to give

FIG. 7.—*Canna*

leave; accordingly on the 18th of July they commenced to make a section along the West Coast of Africa. It was the rainy season; each day would bring them nearer to the equator, and it was scarcely possible to look forward to other than disagreeable times. On the 19th they were off Palma Island, one of the Canaries; then they bore down on S. Antonio, one of the Cape Verd islands, and were at St. Vincent on the 27th of July.

The botany of this island, so noted in the old gazetteers for its wood, water, wild goats, turtles, and saltpetre, was carefully explored. As seen from the sea, the rocks presented a singular appearance, owing to the presence of a thick incrustation at water-mark of masses of calcareous algæ, which either follow the forms of the rocks or occur in rounded masses, their delicate tints of white, light pink, or cream colour considerably heightening the effect. These incrustations are frequently bored by *Lithodomus caudigerus* and other molluscs, and small sponges and Polyzoa occupy the cavities between them and the rocks.

Leaving the Cape Verd Islands, on the 13th of August they were off the Bissagos Islands, and found bottom at a depth of 2,575 fathoms. Continuing to cruise along the coast, on the 14th they were west of the Loss Islands; on the 15th they passed Sierra Leone; on the 19th they

were off Cape Mesurado, still in depths of 2,500 fathoms and on the 21st they had run as far along the Western Coast of Africa as they intended, being then off Cape Palmas, and the *Challenger's* course was shaped for St Paul's Rocks These rocks lie about 1 north of the equator, and in longitude 29 15' W, being about mid way between the South American and African coasts Although rising to a height of some 50 to 60 feet above the sea level, yet they are mere rocks, not more than a quarter of a mile long The sea deepens quickly in the vicinity of the rocks to depths of from 1,500 to 2,200 fathoms The wash of the waves is such that even sea weeds cannot retain their positions on the rocks

Proceeding still in a south west direction, the little group of islands called Fernando Noronha was reached on the 1st of September, and some days were spent exploring it The group consists of a principal island about four miles long by three and a half broad, and several smaller ones, it is situated in the Atlantic, in about lat 3° 56 S, long 32° 22 W, and about 200 miles from the nearest point of the American coast The islands appear to be of volcanic origin the peak on the northern side of the principal island rises to a height of 1,000 feet, it is a mass of bare rock the summit of which is quite inaccessible The cliffs are chiefly composed of columnar basalt The sea depth in the neighbourhood is from 1,000 to 2,000 fathoms Trees abound on the higher parts of the island, and wondrous creepers cluster together in the branches of the trees A species of Cereus was found by Mr Mosely on the cliffs Only one grass (*Oplismenus colonus*) was found on the main island, but although shady, moist places occur about St Michael's Mount, neither on this nor on the main island were any ferns, mosses, or hepaticæ found, and lichens were very scarce Among the principal cultivated fruits are bananas and melons, the latter being very plentiful, and of

Fig 8 —Blown sand Rocks, Bermudas

peculiarly fine flavour Sugar cane, cassava, maize, sweet potatoes, were grown in large quantities The species of land animals on the island are not numerous, but individuals of several of them are most abundant, two species of lizards are recorded from the islands, one being peculiar to the group

On the 4th of September the *Challenger* was some 90 miles south of Cape St Roque, in 2,275 fathoms, with globigerina ooze. On the 8th she was off Parahyba, in 2,050 fathoms, with mud On the 9th the sounding gave a depth of only 500 fathoms off Cape San Agostinho The depth increased off Macayo (September 11) to 1,715 fathoms, diminishing off the mouth of the River San Francisco to 1,200 fathoms, and as the coast at this spot was approached to 700 fathoms On the 14th the *Challenger* was at Bahia, and stopping there a short time she proceeded for a section across the Atlantic from Bahia to the Cape of Good Hope Owing to unfavourable winds and other causes, the little Island of Trinidad an island whose vegetation was then totally unknown, had to be passed by, and the ship's course was directed to the little known islands of Tristan d Acunha, and on the 18th of October she was anchored on the north side of the large island which gives its name to the group This island rises in a range of almost perpendicular cliffs of black volcanic rock, in appearance somewhat similar to that exposed in section on the Grande Curral, in Madeira At their base are *debris* slopes, and a narrow strip of low shore land, on a portion of which lies the settlement Unfortunately, before much even of these slopes could be explored by the landing party, a sudden squall came on the recall was hoisted from the ship, and they had to leave after a visit of only six hours Grasses, sedges, mosses, and ferns were found growing on the cliffs and hepaticæ so abounded as to cover the earth with quite a green sheet, occasional patches of *Phylica arborea* were

seen. This tree, belonging to the family Rhamnaceæ, is peculiar to these islands and to Amsterdam Island, in the South Indian Ocean. *Lomaria alpina*, when found in stony places, bore fertile fronds, while those growing in rich vegetable mould were barren. Some of our common weeds were finding themselves at home, such as the sow-thistle. That lovely little cinchonaceous plant, *Nertera depressa*, was very abundant. Growing round the island was a belt of that gigantic sea-weed, *Macrocystis pyrifera*, which abounds in the southern temperate zone. Single plants often grow to a length of 200 feet, and it is said that they sometimes are met with from 700 to 1,000 feet in length, forming cable-like masses nearly as thick as a man's body. There was no time to explore the high plateau; but one interesting observation was made, indicating the presence of snow on the hills, for while the temperature of the fresh-water ponds at the sea-level gave a result of 54° F., that of the streams running down the cliffs was but 50° F.

They had an opportunity of visiting the two other islands of this group, Inaccessible Island, about twenty-three miles W. by S. of Tristan d'Acunha, and Nightingale Island, about twelve miles from Inaccessible Island. On this latter two Germans were found, who had succeeded in cultivating the ground in the neighbourhood of their dwelling. On both islands *Phylica arborea* was found, and the trees were covered with fully-developed green fruits. A tussock grass, apparently very close to *Dactylis cæspitosa*, of the Falklands, grew in immense, almost impenetrable masses on Nightingale Island, amid these countless penguins had established themselves. It was but with the greatest difficulty that a passage could be forced through such thicket, the grass being too high to allow of the planning of any definite track, and the screaming and biting of the penguins was the reverse of agreeable. This island is never visited except during the sealing season, and is not over one square mile in extent, a veritable speck in the ocean.

The ship's head was now turned for Simon's Bay. Five stations between these points were selected for observation. The depth varied on this line from 2,100 to 2,650 fathoms, the bottom yielding red mud at the greater, and grey mud at the lesser depths. The 28th of October saw the *Challenger* at anchor off Capetown.

Simon's Bay was left about the 14th of December, six weeks having been spent in recruiting and refitting. Even

FIG. 9—Sand glacier, Bermudas

in the comparatively well-worked-out district of Capetown new discoveries were made, of which by far the most important was Mr. Moseley's discovery of the tracheal system in *Peripatus capensis*, an account of which has been published in a late volume of the *Philosophical Transactions*. This tracheal system, though conspicuous in the fresh condition, becomes scarcely visible when the animal has been some time in spirit, and the air has been thus removed, hence the failure of Grube, Saenger, and others to see it. The first soundings during the southern course were taken in the region of the Agulhas Current on the 17th and 18th of December. These soundings would have been naturally logged "greenish sand," but on examination were found to consist almost without exception of the casts of foraminifera in one of the complex silicates of alumina, iron and potash, probably some form of glauconite; this kind of bottom had been met with once or twice, but is evidently quite exceptional. Going still south, Marion Island was visited for a few hours and a considerable collection of plants, including nine flowering species, was made. Dredging near the island gave a large number of species, many representing northern types, but with a mixture of southern forms. On the 30th of December, being then between Prince Edward's Island and the Crozets, the dredge was let down to a depth of 1,600 fathoms, and a vast number of species belonging to the well-known genera *Euplectella*, *Hyalonema*, *Umbellularia*, *Pourtalesia*, as well as two new genera of stalked crinoids, several quite new spatangoids, and several remarkable crustacea were taken.

1874

The new year opened with a storm, and they could not land on Possession Island, on account of the weather; though a dredging in 210 and another in 550 fathoms about eighteen miles to S.W. of the island were made with satisfactory results. On the 7th of January Kerguelen's Island was reached, and the *Challenger* remained there till the 1st of February. During that time Dr. v. Willemoes-Suhm was chiefly occupied in working out the land fauna, Mr. Moseley collected the plants, Mr. Buchanan attended to the geological features, while Prof. Wyville Thomson and Mr. Murray dredged in the shallow waters round the islands with the steam-pinnace. Many observations were made, some on the development of the Echinoderms, and great collections were stored away. On one occasion the trawl

net came up nearly filled with some large cup sponges, probably belonging to the same species as was dredged up by Sir James Clarke Ross many years ago near the Ice barrier On the 2nd of February they were 140 miles south of Kerguelen, and on the 6th they reached Corinthian Bay in Young Island, and had made all arrangements for examining it when a sudden change of weather obliged them to put to sea, though one or two of the party had succeeded in spending an hour or two on shore The most southerly station made was on the 14th of February in lat 65 42 S, long 79° 49 E, when the trawl brought up from a depth of 1 675 fathoms a considerable number of animals Dredging so near the Antarctic circle was, however, not only a severe but a somewhat critical operation the temperature of the work rooms for days averaged seven or eight degrees below freezing point, the ship was surrounded by icebergs, and snow storms from the south east were constantly blowing against her

On the 23rd of February the wind had risen to a whole gale, the thermometer fell to 1 1 the snow drove in a dry blinding cloud of exquisite star like crystals which burned the skin as if they had been red hot and none were sorry to turn northwards This was a period of sore anxiety to all in charge still observations on temperature were carried on the specific gravity of the water was taken daily by Mr Buchanan and soundings and observations were also made on ... The soundings and dredgings while they were among the ice ... to 1 975 fathoms, gave evidence of a very distinct deposit of yellowish clay with pebbles and small stones, and a considerable admixture of Diatoms Radiolarian &c, the former doubtless being a deposit from the melting icebergs Soundings were made on the ... of February, and 3rd and 7th of March in 1 800 fathoms when some very remarkable large sized star fishes were met with On the 13th of March, at a depth of 2 ... fathoms, with a bottom temperature of 0 ... C Holothurians were abundant, as well as many other animal forms

I i —I I I

Melbourne was reached on the 17th of March and some weeks were pleasantly spent, which were all the more refreshing after the hardships of the tour to the Antarctic circle Next Sydney was visited, and here everything was done by the inhabitants to welcome the members of the Expedition that could be done, and there is no doubt that the memory of their visits to our Australian Possessions will linger among the pleasant ones that they will indulge in for years A very careful survey of that portion of the Pacific Ocean that intervenes between the coasts of Australia and New Zealand was required for electric telegraph purposes, and the soundings made by the *Challenger* gave every reason to expect that it would not be ... ere New Zealand would be in telegraphic connection with Europe as indeed it now is. Until the end of June the *Challenger* was engaged on this work but on the 6th of July, 1874 she set out once more on an ocean cruise

Leaving Wellington on the 7th she proceeded under sail along the east coast of New Zealand On the 10th they were about forty miles to the east of East Cape, and continuing their course towards the Kermadec Islands, on the 14th they were off Raoul Island. The specimens brought up from a depth of 6 .. fathoms were just such as one would have expected to find in a similar depth off the coast of Portugal On the evening of the 19th they arrived at Tongatabu one of the Friendly Islands Two days were spent in visiting different parts of the island, and a few hauls of the dredge were made in shallow water off the coast They next made a straight course for Matuku Island the most southerly of the Fijis, where, on the 24th, a party of surveyors and naturalists landed, some others explored the sea along the coast, trawling in some 1 to 3.. fathoms and procuring among other fine things a specimen of the Pearly Nautilus *Nautilus pompilius* which was kept alive in a tub of salt water for some time so as to watch its movements Kandavu was reached on the 25th Levuka was visited on the 28th, and the ship returned to Kandavu on the 3rd of August, to remain for a week The natural history of the coral reefs surrounding the Fijis was examined by the civilian staff, who received every assistance possible from Mr Layard, H M Consul Between New Zealand and the Fiji group only two soundings had been taken to a greater depth than 1 000 fathoms, one off Cape Turnagain, New

Zealand, gave a bottom of grey ooze at 1,100 fathoms, and the other, midway between the Kermadecs and Friendly Islands, gave red clay at a bottom of 2,900 fathoms, the other dredgings and soundings were in depths of from 3 to 600 fathoms, and many of the former yielded an abundance of animal life.

On the 10th of August the *Challenger* left for Api, one of the least known of the New Hebrides, and on the 18th anchored off the island Capt Nares had given a passage from Fiji to eleven men of Api, and two or three of the officers, with an armed party of marines, took the returned labourers on shore. The natives appeared somewhat mistrustful, and were armed with clubs, spears, and bows with sheaves of poisoned arrows, so that it was not thought prudent to go into the forest. The natives were almost entirely naked, and were of rather a savage and forbidding aspect From Api the *Challenger's* course was to the north-westward, towards Raine Island, which is in a breach of the great barrier reef not far from the entrance to Torres Straits A sounding on the 19th, in lat 16 47 S, long 165 20′ E., at a depth of 2,650 fathoms, with a bottom of red clay, give a bottom temperature of 1 7 C (35 1) A serial temperature sounding was taken to the depth of 1,500 fathoms, and it was found that the minimum temperature (1 7 C) was reached at a depth of 1,300, and that consequently a stratum of water at that uniform temperature extended from that depth to the bottom

Serial temperatures were taken on the 21st 24th, 25th, 27th, and 28th of August, in 2,325, 2,450, 2 440, 2,275, and 1,700 fathoms respectively, and in each case the minimum temperature of 1 7 C. extended in a uniform layer, averaging 7,000 feet in thickness, from the depth of 1,300 fathoms to the bottom. The area over which this temperature existed has been called the "Melanesian Sea," and it is evident that there is no free communication between it and the outer ocean to a greater depth than 1,300 fathoms, the encircling barrier being complete up to that point. The animals procured in this sea were few in number, but sufficient to show that the existence of a fauna is not impossible in the still bottom water of such an inclosed area, though, as in the Mediterranean, such conditions do not appear to favour life

On the 31st Raine's Island was visited, and found to be just as described by Jukes, a collection of the birds breeding there was made, and the next day, the 1st of September, the ship was at Cape York Proceeding thence across the Arafura Sea to the Aru Islands, Dobbo, a town on the Island of Wamma, was reached on the 16th After a few days spent in shooting some birds of Paradise and getting an idea of the natural history of the place, they proceeded to Ke Doulan, the principal village in the Ké group, thence to the Island of Banda, where they remained a few days, and thence to Amboina, which was reached on the 4th of October In some of the dredgings between Ke and Amboina a wonderful assemblage of forms were met with, not only new Pentacrinoid forms, but many new vitreous sponges—Echinoderms, Crustacea, &c. From Amboina they went to Ternate, and thence across the Molucca Passage into the Celebes Sea, by the passage between Bejaren Island and the north east point of Celebes Crossing the Celebes Sea, Zamboanga was reached on the 23rd, and the Sulu Sea on the 26th. Capt Chimmo's observations on this basin-sea were confirmed. Ilo Ilo was visited on the 28th, and proceeding by the eastern passage round Mindoro, Manila was made on the 4th of November, and after a short stay at the Philippines, Hong Kong was made head quarters for a time During the *Challenger's* stay here Capt Nares received a telegram offering him the command of the Arctic Expedition This was a great blow to all of the party. Though sorry to part with one who had so far brought the expedition successfully on its way, the importance was fully recognised of having a man of his character and experience in command of the North Pole Expedition. Capt Thomson, who was already on the China Station in command of the *Modeste*, took Capt. Nares's place.

1875

Hong Kong was left on the 6th of January, with the intention of sailing to the region of the Equator, then making a series of stations parallel to it, for a distance of some 2 000 miles, and eventually going north to Japan Proceeding to the middle of the China Sea, a series of temperature soundings were taken, the temperature at the bottom of 1,200 fathoms being 36 I This is accounted for by Chimmo's statement that the China Sea is cut off, by a barrier rising to a height of 800 to 900 fathoms below the surface of the water, from communication with the waters of the Antarctic Ocean Passing along the west coast of Luzon, the *Challenger* entered the Panay Sea, where further observations were made, visiting Zebu, the first known locality for the 'Venus Flower basket,' where some fine specimens of this sponge were obtained in the dredge Next the ship made for the little island of Camaguin—between Mindanao and Bohol to inspect the active volcano there on This volcano was ushered into existence on the 1st of May, 1871, and presented at the time of the *Challenger's* visit the appearance of an irregular cone of 1 950 feet in height, its base was gradually extending, and had covered the town of Catarman From Camiguin the *Challenger* went along the west coast of Mindanao to Zamboanga, which was (for the second time) reached in the last week of January (29th A little party of sportsmen were sent off to camp out in the forest within riding distance of the ship, visits were paid to them from time to time, and they thoroughly enjoyed their brief sojourn in the heart of a most exquisite little bit of tropical scenery, and surrounded by multitudes of monkeys, galeopitheci, and many more of the strange denizens of such woods Thus was a pleasant week spent, and with some regrets Zamboanga was left on the 8th of February The following day was spent in the strait between Mindanao and Basilan The view of both islands from the strait was extremely beautiful from the luxuriance of the vegetation which filled up the gullies and mantled over every basalt ridge and peak up to their very summits On the 9th the party were off Cape San Augustin and in view of Balut, the finest of the Sarangani Islands, with a fine volcanic cone thickly wooded to the top On the 10th they had a very successful haul of the dredge off the Island of Tulur, in 500 fathoms, getting many specimens of three or four species of Pentacrinus, with stems two or three feet high About this time the wind felt very light and uncertain, and a strong current was setting them down towards the coast of New Guinea The coal supply was running short, and was required for dredging and sounding up to Japan, the nearest place for a fresh supply, so Capt Thomson determined to make for Humboldt Bay On the 21st of February, still drifting southwards, they were opposite the delta of the great river Amberno, which rises in the Charles Louis Mountains, a splendid range in the interior of New Guinea, upwards of 16,000 feet high, and falls into the sea at Cape D'Urville, to the east of the entrance of Geelvink Bay Night was falling on the 23rd as the *Challenger* cast anchor just within the headlands of Point Caille and Point Bonpland Next morning, shortly after daybreak, the ship was surrounded by about eighty canoes, each from 15 feet to 20 feet long and with crews of from four to six men each There were no women or children among them. The men were unusually good looking for Melanesians, and wonderfully picturesque, they seemed on an average about 5 ft. 4 in. in height, features tolerably good, nose rather thick and flat, eyes dark and good, expression agreeable, mouth large, and lips rather full, betel and chinam chewing had destroyed their teeth and dyed their gums crimson, and their ear lobes were greatly lengthened by earrings Their

hair is frizzled, not woolly, very thick, and worn in the shape of a huge round mop; it was partly bleached by lime, or coloured red by lime and ochre; black and white feathers and coronals of scarlet Hibiscus flowers were worn on their heads; the face was smeared with black or red pigment; with the exception of a few ornaments the body was entirely naked; the skin dark brown in the shade, warmed to a rich red brown in the sunlight. A band of tappa, variously ornamented, encircled the middle of the upper arm on both sides, and into this they stuck, towards the outside of the arm, large bunches of the fresh green and white leaves of a beautiful narrow-leaved Croton. The natives were well armed with strong bows and arrows, the latter five to six feet long, with heads bristling with barbs. In almost every canoe there were stone hatchets mounted on hard wood handles, closely resembling those found in Denmark; they were made of a hard, close-grained green stone, taking a jade-like polish. The canoes had generally a grotesquely carved prow, the paddles being of hard wood, leaf-shaped, and often prettily carved.

In the course of the afternoon Capt. Thomson and Prof. Wyville Thomson went in the galley to an island where there was a village, to ascertain the temper of the natives and see if it were safe to go about freely. They were rowed to a sandy beach and made signs that they wished to land, but the whole population, consisting chiefly of women and boys, all armed with bows, turned out with the most determined demonstrations of hostility. The women were not prepossessing; the young girls were perfectly naked, and were no ornaments; the matrons wore a fringe of rough bark cloth round their loins. The village consisted of some twenty to thirty huts, some on land under the trees, but most of them built on a platform raised a few feet above the surface of the sea on piles and communicated with the shore by planks removed at pleasure. Another boat sent off to get sights had been caught hold of by the natives and plundered, but no attempt at retaliation had been made by the crews. Had things gone on well, the *Challenger* would have remained at Humboldt Bay for five days, but Capt. Thomson made up his mind not to submit to the pilfering that was going on, nor to risk the chance of a rupture, and after careful consideration and consultation went on towards Admiralty Island the same evening. During the afternoon the Captain, Prof. Wyville Thomson, and Mr. Murray managed to land on the shore of the bay by going in a canoe with some natives, and during an hour's ramble on shore, Mr. Murray had the good luck to see three of the wonderful crested ground pigeons of the genus *Goura*, which are nearly as large as turkeys.

During the next week the ship gradually made her way, with light winds and heavy rains, and close depressing, equatorial weather, past the Schouten Islands and Hermit Island towards Admiralty Island, where it arrived on the 3rd of March, and anchored in a lovely bay in eighteen fathoms; this they called Nares Bay, in compliment to the head of the Arctic Expedition, their former captain. The natives are Papuan Melanesians, but partake more of the characters of the Papuans of New Ireland and New Britain than of those of New Guinea. Here bows were unknown and the natives used spears, with heavy heads of obsidian and light shafts 6 to 7 feet long; they also use long sharp knives or daggers of obsidian, and almost every man had over his shoulder a neatly mounted little adze made of a small piece of hoop iron; a few carried implements of the same form but the cutting part made of a piece of a thick shell ground down. Here the natives made no great opposition to the party landing, only hurrying them past or away from their villages and warning their women to keep out of sight. Sometimes the curiosity of the women would overcome their discretion, and little groups would come out to see the strangers. These were anything but pleasing looking; they wore no clothing except two fringes of grass or palm-leaves. In the course of a few days all the party were quite at home with the natives and went and came as they pleased. The natives were found to be totally ignorant of the use of tobacco and pipes, but though they showed many good points yet there are other natives' suspicions that they disposed of their dead in a very economical though hideously repulsive way. Some of the small islands literally swarmed with the beautiful large nutmeg pigeons.

On the 10th of March the *Challenger* steamed out of Nares Harbour, intending to call at one of the more western of the Caroline Islands, and perhaps at some of the Ladrone group; but the explorers were so very unfortunate in the wind that they were driven to the west of both groups, and never again saw land until they sighted the Japanese coast on the 11th of April. This cruise was by far the most trying one during the commission. The weather for the greater part of the time had been excessively sultry and depressing, and before entering on it

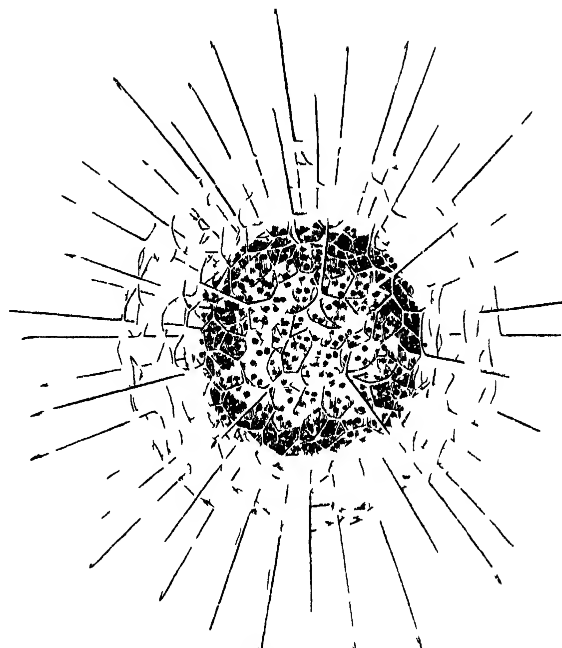

Fig. 10.—Radiolarian.

they had been nearly a year in the tropics. The section from the Admiralty Islands to Japan, 2,750 miles long, was practically meridional; the observing stations were twelve in number and pretty regularly distributed. The greatest depth was found on the 23rd of March, in 4,575 fathoms. With the exception of two soundings taken by the *Tuscarora* off the east coast of Japan, in 4,643 and 4,655 fathoms respectively, this is the deepest trustworthy sounding on record. A second sounding to check the first gave 4,475 fathoms, and in this the tube of the sounding machine contained an excellent sample of the bottom, which was of a very peculiar character, consisting almost entirely of the siliceous shells of Radiolaria. In these the body may have a more or less fully developed external siliceous skeleton, minutely fenestrated, and often presenting very remarkable and beautiful forms (Fig. 10), or the skeleton may be essentially internal and be formed of a number of siliceous spicules radiating from a centre, round which the sarcode is accumulated, as in *Xiphacantha* (Fig. 11). Or again they may give off a set of finely anastomosing branches which form one or several concentric lacey shells, which invest the sarcode nucleus as in *Haliomma*

(Fig 12) These lovely forms occurred in such numbers in this sounding as almost entirely to mask the red clay

The most marked temperature phenomenon observed in this part of the cruise was the presence of a surface layer of water at a depth of 80 fathoms and a temperature above 77° F extending northwards from the coast of New Guinea, about 20°, and westward as far as the meridian of the Pelew Islands The greater part of this vast mass of hot water is moving with more or less of rapidity to the westward

The travellers, weary and worn out by their assiduous labours in the Tropics, had a welcome and a well deserved rest at Japan The wonders of Yeddo and the freshness of the climate soon restored them to vigour Short excursions were made and various towns and villages were visited A cruise was made after a time to Kobe and along the south-west coast of Nipon, and on the 16th of June the *Challenger* left Yokohama and ran an easterly course between the parallels of 35° and 40° north latitude as far as the meridian of 155° east She then went nearly directly southwards and reached Honolulu, one of the Sandwich Islands on the 27th of July

Between Japan and these latter Islands twenty-four observing stations were satisfactorily established At the first station, just forty miles to the south of Nosima Lighthouse, they had a successful trawl and brought up a mass of starfish and other Echinoderms that was found a giant hydroid polyp apparently referable to the genus *Monocaulus* The hydranth was 9 inches across from tip to tip of the expanded tentacles, and the hydrocaulus or stem was 7 feet 4 inches high, with a diameter of half an inch This wonderful form was found once again nearer to Honolulu The deepest sounding got off Japan was 3,950 fathoms ... The temperature observations gave a ... result ... surface temperature had fallen to 6... and the belt of water above 50° F was reduced in depth to considerably less than 100 fathoms, while all the isotherms, at all events to a depth of 300 fathoms, rose in proportion There seems to be little doubt from a comparison of the American temperature results with those of the *Challenger*, that this sudden diminution of temperature is due to a cold surface flow from the ... of Okhotsk and possibly attaining its maximum at the season of the melting of the snow over the vast region drained by the Amoor and Siberian Rivers with ... overflow

The soundings from Yokohama to Honolulu ... uniform as to depth ... 2,850 fathoms and the bottom was pretty ... red clay In some cases the trawl came up half filled with large lumps of pumice which seemed to have drifted about till they became waterlogged The red clay was also found full of concretions mainly consisting of peroxide of manganese round oval or mammillated and very irregular, varying in size from a grain of mustard seed to a large potato On breaking these they are found to consist of concentric layers having a radiating fibrous arrangement and usually starting from a nucleus consisting of some foreign body, such as a piece of pumice or a shark's tooth, or such like

A delightful fortnight was spent on the Sandwich Islands, numerous excursions were undertaken In the Government Library at Honolulu there was a splendid collection of scientific books, which enabled many points in the natural history of some of the species found to be verified On the 11th of August Hawaii was visited and the crater of Kilauea was explored On the 19th Hawaii was left, and the course of the *Challenger* was due south to Tahiti Many soundings and dredgings were made on the way the average depth being 2,800 fathoms, with a bottom of red clay, and many things of great interest to the biologist were discovered Tahiti was reached early in September, and amid the charms of this island, by some better known as Otaheite, the time sped quickly until October every opportunity was made use of to get acquainted with the productions, climate, geological structure, and inhabitants of the island Leaving it on the 2nd a section was made across to the island of Juan Fernandez a distance of about 4,000 miles with an average depth of 2,160 fathoms Juan Fernandez was reached on the 13th of November, and two days were spent exploring every corner of it, and large collections were made The ship anchored in the harbour of Valparaiso on the 19th Three weeks were here spent to recruit, and then the *Challenger* ... on the 10th of December, started on a cruise round Cape Horn to the Falklands

1876

The Falkland Islands were reached about the 10th of January and some three weeks being spent in explorations among the islands on the South American Coast, Monte Video was visited on the 15th of February, when, after a week's sojourn homeward was the cry, and on the 23rd the *Challenger* left for her last section across the Atlantic in the direction of Ascension Island and St Vincent At the Cape de Verd Islands she once more was in familiar waters and had encircled the world The former was reached on the ... th of March, and a week was spent at George Town when stores were completed and a few supernumeraries taken on board On the 18th of April St Vincent was reached and the final start for home made on the ...th, her arrival at Spithead on the 24th of May is now a matter of history We are glad to be able to report that all of both staffs are in the enjoyment of perfect health

This sketch of the *Challenger* cruise has, from the very necessity of the case been an imperfect one time and space both failed or we would have gladly told of visits to Heard Island the strange breeding place of the giant albatross of fights with sea elephants and of many of the new and rare animals found in the depths of the three oceans We would here also like to have subjoined a sketch of the chief scientific results of the voyage but perhaps it were better left undone, for we know that a "Narrative of the Cruise of the *Challenger*" from the able pen of the head of her civilian staff, is already in an advanced state of preparation From the glimpses we have got of it from the beauty of the illustrations some of which adorn this sketch) that will appear in it we feel sure that it will be one of the most deeply interesting as well as fascinating books published It will be not a mere enumeration of events, but contain, as well descriptions and figures of all the new forms forming a most worthy contribution to Physical Geography, to Ethnology and to Zoology and Botany

In conclusion we append a tabular abstract of the voyage of the *Challenger*

and gurnard, which lie in well-arranged confusion at a little distance, whilst in No 186, a carefully painted dog fish and skate are seen lying on some crab pots In No 234, 'Crabbers,' there is abundance of motion in the boat which is just taking in a wave over the bows as one of the fishermen hauls in the crab pot, but what shall we say of the fine male crab which he is extracting? The face of the crustacean is towards the spectator, but will it be believed that an artist of Mr Hook's experience has actually placed the huge claws *behind* the legs, instead of in the *front*! Think of the outcry there would have been, if in that over discussed horse in the "Roll call," about whose action nobody could agree, the artist had chosen to put the fore legs where the hind limbs should have been it would have been treated as an insult to common sense, for every one knows, or thinks he knows, the points of a horse But a mere crab, poor *Cancer pagurus*, what does it matter where his nippers are placed? We sincerely hope that when Mr Hook has occasion to paint a live lobster he will not paint it red, although this would be by far the more trivial error of the two

It is needless to say anything of Mr T S Cooper's cattle pictures, for we have seen the same kind of thing as long as we can remember In 243 'An Inquisitive Magpie," Mr Jones has some brown sheep in a brown atmosphere, contemplating a stuffed magpie on a hurdle the picture is hopelessly "skied but it may be satisfactory to the artist and to Mr P A Duffy, whose excellent 'Flood in the Dargle hangs next at a similar elevation, to know that their works help materially to tone down the too advancing brown of the tree trunk in Mr Leighton's "Daphnephoria, hung immediately below

"Early Summer 105, by Mr H W B Davis A, is a clever landscape with Devon cattle, but by far the greatest work which has ever proceeded from his brush is 'Mares and Foals, Picardy' (557, a picture which may challenge comparison with any similar subject by Landseer In the foreground a foal, bitten by a fly plainly visible on its neck, is plunging wildly over another foal which is lying down, the centre figure is a large white mare whinnying and showing her teeth at another member of a group which seems generally out of temper whilst the mare and foal to the left in repose, are simply perfection The great mass of white in the centre is most difficult to manage, and in certain lights there is something not altogether satisfactory about the shoulder on the off side, but when the direct glare of the sun does not fall on the picture, this apparent defect disappears

Mr B Riviere has not been fortunate with his Ducks in a 'Stern Chase (513 and the art critics do not seem favourably disposed to his (496) "Pallas Athene and the Herdsman's Dogs but putting the figure of the goddess out of the question, the dogs, which are uncommonly like wolves, are really well drawn, and the attitude of the one rolling on its back is excellently given There is much humour in the expression of the bull mastiff looking down on the skye terrier in Mr O Weber's 'How do you do (416), and as they are stated to be portraits, we cannot quarrel with the head of the former, but his chance of a prize at a dog show would be small In 'Home Ties' (435), Mr E Douglas gives us a foxhound and litter in kennel, and in 556, 'A Bagged Fox, a capital fox terrier, standing on and watching intently the movements in a sack, from which the bagged fox is just gnawing his way out, in the foreground are two red herrings tied to a cord indicating that the hounds are generally hunted on the drag, and that a fox is an unwonted luxury probably he has been purchased to give a brilliant wind up to the season Two other sporting pictures 231, by W H Hopkins, and 557 by S Pearce, are commendable

Mr Ansdell has abandoned Spain this year, and all his pictures, but one represent Scotch scenes In 214 we have the well known black and white ponies, whilst 619 represents some half drowned sheep recovered by the shepherds the foreleg of the sheep standing upright are absurdly small and out of all proportion The colly-dog which has just killed a hill fox caught in the act of devouring a lamb 524 is painted in that artist's usual style for in dogs he has now no rival, but we miss the life and expression which Landseer used to give to his canine friends Mr P Graham's 'Moorland Rovers' (585), a couple of shaggy Scotch cattle would look better if they were painted on a smaller scale, and the green of the reeds in the foreground strikes us as somewhat vivid in colour

Mr Heywood Hardy's 809 is a somewhat ambitious attempt to represent an extremely difficult subject—the animals coming to Noah's ark It would appear that the artist started with the intention of confining his choice to members of the African or Ethiopian fauna there are ostriches giraffes, African elephants and buffaloes, sable antelopes Dorcas gazelles and other species whilst the most obtrusive figures are those of two hippopotami, one of which is opening its enormous jaws to their fullest extent The deep red of the interior of the beast's mouth has unfortunately necessitated a very serious departure from the original plan and led to the introduction on the right of the picture of two scarlet *Ibis* or *Ibises*, whose office is clearly to tone down the red of behemoth's mouth We are not altogether satisfied with the presence of the Syrian bear, the horse, and the wild ass in such company The foreshortening of the pelican's wing on the left is also incorrect and, indeed, the birds in general are not satisfactory but we have to thank Mr Hardy for clearing up a point which has hitherto been unexplained We never could understand why the raven never returned to the ark but after viewing the bird which has looked up wistfully at Noah's feet, and evidently wondering how he is to get up there without anything to walk upon we see that it is only too plainly From the moment that Noah inhumanly 'sent him forth his minutes were numbered, a couple of despairing flops of his incapable wings, and unless Noah promptly lowered a boat, the corpse of the corpse devourer must speedily have become the sport of the waves which then united the Black and Caspian Seas But with all its defects, Mr Hardy's picture is a most meritorious attempt at portraying animals as they really are, nearly every species has evidently been drawn from the live specimens in the Zoological Gardens and we sincerely trust that the artist will persevere in the line which he has selected

Miss A Havers has been very fortunate in her delineation of geese in 'Goosey, Goosey Gander' (1260) a girl sitting on a foot bridge at evening, watching a flock of geese wading in the burn one of the flock is leaving the rest and waddling off to the wrong side of the water It is not every one who can paint a goose, and it would be difficult to imagine a more accurate representation of the ungainly motions of that despised bird Equally good in its way is the rendering of the action of a mule just at starting, in Mr W J Hennessy's 'Fete, Normandy" (523 which has moreover a charming composition

It is sad to have to notice such painful failures in animal painting as those of Mr C Landseer, R A, "A Watch Dog" (420), and Sir F Grant's "The Muckle Hart' (1341), in the latter the recumbent stag has hardly one of his tynes correctly drawn, and the hind in the distance is a fearful and wonderful beast

With regard to the Statuary, it is difficult to find a place in the lecture room, whence a good view can be obtained of J E Boehm's enormous equestrian group of St George and the Dragon, but the dragon deserves notice as being a compound of several existing reptilian forms, thus approaching reality as far as is possible with a semi-mythical monster. The body of the dragon is that of a crocodile, the neck and head are those of the Cerastes or horned viper, whilst the wings are modelled after those

of the small flying lizard. Mr. G. A. Carter's "Group of Red-deer" (1405) is not a great success, but it will probably look better when executed in silver. There is much merit in Mr. W. Pitha's "Polar Bears" (1455), in which the artist has coloured the snouts and slightly washed the limbs of the animals with yellow to relieve the deadness of such a mass of white, an excusable innovation in the present instance. And last in order we come to two admirable models of "A Wild Boar" (1501), and "A Bear" (1507), by Mr. Joseph Wolf, whose reputation as a delineator of animal life with the brush is unrivalled, but who has never till now turned his attention to modelling. The attitude of the boar is excellent; his face is devoid of any expression, although he has evidently partaken of some vegetables whose remains lie at his feet, but withal there is no sign of enjoyment or satisfaction. It is otherwise with the bear, who has been devouring honey-comb, and who is now licking his chops with an expression worthy of a gourmand, showing that the good things of this life are by no means wasted upon a gentleman of his appreciation. And with this we close our notice of animal life at the Academy, congratulating artists in general upon the increasing tendency to paint their subjects from nature instead of evolving them out of their own inner consciousness. TWO NATURALISTS

THE ETHNOLOGY OF THE PAPUANS OF MACLAY COAST, NEW GUINEA

IN December 1873 when at Batavia I received from the Russian traveller Von Miklucho Maclay reprints of two articles upon the East Coast of New Guinea and its inhabitants, of which I made a short abstract for NATURE (Feb. 26, 1874) during my voyage from Java to Atchin. The following is the substance of one of two supplementary papers on the same subject,[1] which have been lately sent to me, by Dr. Maclay, from Johore on the Malay peninsula, which it would be imagined should be all the more interesting, as much which is to say the least doubtful has lately been published about New Guinea and its natural productions.

The former papers dealt with the individual characters of the Papuans, while in the present article the food, weapons, dress, dwellings, and daily life of this people will be treated of.

The Food of the Papuans.—That of the inhabitants of Maclay Coast is principally of a non-animal nature, consisting of fruits and vegetables, of which a list is subjoined in the order of their domestic importance.

The Cocoa-nut (*munki*).—This plays a most important part in the economy, as it is obtainable all the year round. The trees are seldom to be met with in the mountain villages, but are numerous on the shores of the neighbouring islands, though here they are confined to plantations around the houses. A favourite dish which never fails at feasts is *munkila*, a kind of porridge made of the grated kernel of the nut steeped in the so-called "milk." Curiously enough, the preparation of cocoa-nut oil is unknown.

The Dioscorea (*ajan*) is much cultivated in the plantations, and is in condition for food from August till January. It is boiled in water, or when this is difficult of carriage, roasted in ashes. It forms the principal article of diet during the above-named months.

The Collocasia (*bau*) is the main article of food from March to August. Like the *ajan*, it is either boiled or baked. Pounded up with grated roasted cocoa-nut, it is made into a kind of cake, which is in great request at feasts. The leaves of the plant are also eaten.

The fruit of the Convolvulus (*degargol*), of which there are two varieties, one red, the other white, is principally in season in September and October, and is either stewed or baked.

Although no less than eight or nine varieties of Banana (*mogá*) were met with by Miklucho Maclay, owing to its limited cultivation the fruit is a comparative rarity. The lower part of the stem and the roots of the young plants are also eaten.

On account of the rare occurrence of the Palm affording it, sago (*buam*) is rather a dainty seen only at feasts, than an article of daily diet.

The Sugar-cane (*dn*), which attains a magnificent growth in New Guinea, the edible portion being not infrequently fourteen feet high, is chewed with the greatest zest by men, women, and children from October to February.

The Bread-fruit (*boh*), though not particularly sought after, is collected and eaten stewed or roasted.

The *Oiam* is the fruit of a tree which Dr. Maclay had no opportunity of seeing. This fruit is hung in great baskets upon the trees in the forests. From the pulp and the kernel of the crushed seed there is derived by fermentation an acid unpleasantly smelling sauce, which is considered a great delicacy.

The Canarium commune (*Keng-ii*) is collected in May, June, and July, dried, and its seed stored.

The fruit of the *Pandanus* (Screw Pine) and *Mangifera* (mango) also occurs, but very sparingly, on Maclay Coast.

Animal food is of but rare occurrence. The following animals are, however, the most usual sources of food:—

The Pig.—This, a descendant from the wild New Guinea species, is bred in the villages. When young it is striped, but with age it becomes black. The ears are erect, the snout sharp, and the legs long. Pigs are only killed on festal occasions, and then one suffices for two or three villages.

Dogs are kept by the Papuans principally for the sake of their flesh, which, though of fairly good flavour, is, nevertheless, somewhat dry.

The flesh of the Cuscus (*mai*) is considered a great dainty, although it has a strong smell.

Fowls, although they occur in the villages, are but seldom eaten, and as they exist in a semi-wild state their eggs are not often to be obtained. During a stay of fifteen months Dr. Maclay only saw two eggs in the various villages which he visited.

From the large lizards (Monitors) a white and tender meat is obtainable.

All insects without exception, especially large beetles, are eaten, either raw or cooked, by the Papuans.

As regards fishes, the larger are caught in nets, while the smaller are killed by harpoon at night time.

Various molluscs and other shell-fish are collected on the coral reefs at low water by the women and children of the villages.

As the existence of salt is unknown here, the Papuans cook their food with a little sea-water, generally one-third to two-thirds fresh water; and the inhabitants of the hills never omit to take away with them a bamboo filled with sea-water when they visit the coast. The Papuans have, nevertheless, a substitute for salt, for they collect the tree-trunks which, after soaking for a while in the sea, are cast up at high tides, dry and burn them, and thus procure therefrom a saltish tasting ash.

The manufacture of intoxicating drinks is, moreover, not unknown among the Papuans. They take the stem, leaves, and especially the root, of a certain shrub called "Keu" (*Piper methysticum*[1]); this they chew, and the resulting mass, when sufficiently masticated, is spat out with as much spittle as possible into a cocoa-nut shell. A little water is added to this, and, after the dirty green looking brew has been filtered through some grass, the filtrate, which is very bitter and aromatic, is drunk off. This liquor does not taste particularly good, as is proved by

[1] "Ethnologische Bemerkungen über die Papuas der Maclay-Küste in Neu Guinea." Reprinted from the *Natuurkundig Tijdschrift* of Batavia.

[1] A small bush equal to that mentioned to New Guinea.

the grimaces of the natives as they drink; very little, too, goes a long way, for a small wine-glassful suffices, in half an hour, to make a man unsteady upon his legs. Old people only are allowed to indulge, for it is strictly forbidden by custom to women and children. The Papuan *keu* appears to be identical with the *kava* of the Polynesians, only these latter add more water.

The *cuisine* is in every way more elaborate than among the Polynesian aborigines, both as regards variety of dishes and the use of earthenware. Though food is mostly prepared with sea-water, the Papuans, nevertheless, know how to roast flesh or fish, or bake it, enveloped in leaves, in the ashes. As on account of the climate cooked food will not keep long, the Papuans either roast (e.g., in the case of the Colocasia and Dioscorea) on the morrow the remnant of that which is left to dry, or *vice versa*, as is the case with fish, which is fried immediately after it is caught, and stewed with vegetables on the following day. By this means the millions of mildew spores and mycelia which in a few hours invade and pervade all food, whether roast or boiled, are arrested in development, and so rendered harmless. The men help the women in the preparation of food; in fact, on festal occasions and on the entertainment of an honoured guest, this is done entirely by the men alone. On ordinary occasions the husband cooks for himself alone and the wife for herself and the children apart. The two sexes *never* eat at the same hearth, or out of the same dish.

The domestic utensils consist of earthenware pots of various sizes, and of wooden dishes. They are of the following varieties:—

Pots (*wab*).—These are usually of the same shape, being almost round, and tending somewhat to a point at the bottom. They are made in a few coast villages and in the neighbouring islands, and, though generally prepared with great care, bear but few ornamentations—these consisting either of straight lines, rows of dots or small curves, evidently impressions of the nails. The mountain people do not understand this manufacture, and so must obtain their pots either by present or by barter.

The wooden utensils (*tabir*) consist of large round or oval plates and bowls, and seem very cleverly made, considering that the only tools used in their construction are either of stone or of bone. They are finally smooth polished with fragments of shells, and a black dye is then rubbed in. The "tabir" forms, with the weapons, the most important possessions and articles of barter for the Papuan.

The shells of the cocoa-nut (*ure*) are used as plates by the lower members of a family, as it is only for the father of the family or for a guest that food is served in the large wooden bowls.

A kind of fork (*aursan*) is used at meals, consisting of a pointed stick. Three of these are sometimes tied together, and are then generally carried in the hair, as they also serve the purpose of head-scratchers.

The *kai* is a kind of spoon made from a cocoa-nut or mollusc shell, while the *schelun* is made from a flat splinter of kangaroo or pig's bone, and can be used either as a knife or shallow spoon.

A very important implement, the *jaur*,—is made merely from a smooth shell, in which teeth are cut with a stone. This is used to grate the albumen of the cocoa-nut, which is usually only eaten in this form.

The implements and arms are as follows:—"If we look at," says Maclay, "their buildings, their *pirogues*, or canoes, their utensils, and their weapons, and then cast our eyes upon the stone axe and some fragments of pebbles and shells, *we must perforce be struck with astonishment if only at the great patience and skill displayed by these savages*." The axe, which, though their chief implement, is, no one will deny, a tool simple enough, consists of a hard, grey, green, or white stone, which has become smooth and sharp by long polishing. Hatchets have been seen by Maclay in the "Archipelago of Contentment" which were made out of a thick clam (*Tridacna*) shell, instead of from stone. A portion of the stem of a tree which has a branch passing off at an angle, somewhat like the numeral 7, is hewn off, and upon the branch, which has been cut off short and shaven flat at the top, the stone is laid horizontally and bound fast with lianas or various kinds of tree barks. Such an implement can only be used to advantage by one accustomed to handle it; otherwise, either the stone is broken or nothing results. The aborigines, however, can with their axe, having a cutting edge of only two inches in breadth, fell a tree trunk of twenty inches in diameter, or carve with the same really fine figures upon a spear. Every village possesses a large axe or two having a cutting edge about three inches broad and which is wielded with both arms, while the ordinary axe of two inches edge is employed with the right arm only. The stone of the hatchets, a kind of ... ite, is confined to the mountain people, and is not found in superfluity. Each adult is in possession of one good axe, the large ones being kept by their owners as things of the utmost value and rarity.

Fragments of flints and of shells are used to put the finishing touches to work done in the rough with the stone axe, the shells being preferred to the flints, as being not so brittle. All sorts of devices can be carved upon bamboo with shell fragments. The great combs of the Papuans and the bamboo boxes in which the lime for betel chewing is kept, as well as their arrows, furnish instances of this art.

The *dongan* is a pointed or flatly split bone, having the shape either of a dagger or of a chisel. For the first-named part in the bones of the cassowary and (but rarely) those of man are used, while those of pigs and of dogs are employed for the latter form. The "dongans" are used for cutting either raw or cooked fruit, and are generally carried on the arm, being supported by the armlet.

A knife is made from the bamboo by removing the inner woody fibres at the edge of a fragment, so that only the sharp siliceous outer part is retained. With this meat and fruit and vegetables are cut up, while the *dongan* is never used for cutting, but only for splitting and piercing.

The weapons comprise:—

1. The *ararr*, a spear used for throwing, about 6 ft. 8 in. in length, and made of a hard, heavy wood. It is the most dangerous and most universally used of the Papuan weapons.

2. There is also a longer, but lighter, spear the *sarauru*, tipped with a sharpened piece of bamboo, which after a victim has been struck, breaks off from the shaft and remains in the wound.

3. The *urar* is a bow, about two yards long, the string of which is made from bamboo.

4. The arrows, *aral*, are about one yard long, of which the tip is as much as a third or a quarter of the shaft in length, and is sometimes provided with barbs.

5. A most dangerous kind of arrow, *ferom* by name, is of the same size as the preceding, but resembles the *sarauru* in having a broad bamboo tip. For catching fish there is yet another variety of arrow, the *saran*, provided with four or five points. When fishing by torchlight, the Papuans use the *jur*, a harpoon with numerous tips of hardened wood, and furnished, in order that it may not sink, with a bamboo shaft.

The inhabitants of the neighbouring islands *Bili Bili*, *Jambomba*, *Graged*, *Tiara*, &c.—possess in addition large shields, about a yard in diameter, made out of a hard wood, and ornamented with carvings. Miklucho Maclay's coast neighbours had nothing of the kind. In some of the villages he saw long flat sticks, about a yard

and a half in length, which must be wielded, much like the large ancient swords, with two hands [1]

Sling-stones are also in use in time of war. The principal weapon of warfare, however, is the above mentioned *chadga*, which is dangerous up to a range of from thirty five to forty paces. The arrows can scarcely be considered dangerous above fifty paces range, because they are too light. In war time, and in hog hunting, the tips of the spears and arrows are rubbed with a red earth, but the Papuans in this neighbourhood do not poison their arrows.

Regarding the dress and ornaments of the Papuans the sole article of clothing of the men is the *mal*, a kind of cloth prepared from the bark of trees, having a length of more than three yards and a breadth of about a quarter of a yard. This article of dress is manufactured in a way similar to that of the *tapas* of the Polynesians, the outer layer of bark is detached, and then beaten with a piece of wood upon a stone until it becomes soft and supple, after which it is dyed with a red earth. It is worn thus: one end having been held fast on the belly, at the navel, the cloth is passed between the legs, and then carried several times round the waist, the end being finally tied with the first end in a knot at the back. As much traction is exercised upon the part which is pushed between the legs, the anterior end comes to hang down in front. The corresponding dress of the females, also called *mal*, consists of fringes about half a yard long, fastened to a girdle, which hangs down in thick clusters as far as the knees, and does not embarrass the movements of the body. This garment is generally dyed in black and red horizontal stripes. In some villages the *mal* of the girls up to the time of marriage consists of a girdle, to which two bunches of dyed bast are attached, one hanging down in front, the other over the middle of the buttocks, and when they sit down they carefully pull the hinder and longer bunch between the legs. These young ladies also carry on either side of their buttocks ornaments of shells and coloured fruit stones. Besides the *mal*, the Papuans possess long and broad pieces of cloth similarly prepared, which they wear over the shoulders in the night and early morning, as a protection against cold.

The ever constant companions of the Papuan are his *[illegible]* and his *[illegible]*. The former is a small bag carried round the neck, containing tobacco and various small articles; while in the latter, which is larger, and is slung over the left shoulder, he carries a box of quicklime for betel chewing, his *[illegible]*, *[illegible]* and *[illegible]*, shells, and bamboo boxes containing red and black dyes and other necessaries. These bags are woven out of variously coloured threads, and ornamented with shells.

The men carry on the upper arm, above the biceps, bracelets called *[illegible]*, artfully woven out of bark or grass, and ornamented with shells. Stuck in such a ring the *dongan* is carried. Similar rings, or "bangles"—*[illegible]*—are worn above the calves. A highly prized ornament, worn hanging from the neck over the breast, is the *[illegible]*, wild boar's tusk.

The men also wear broad earrings of turtle shell or of wood, or in default of these, pieces of bamboo, longish stones, or flowers. The women have two kinds of earrings. From either ear lobe hangs one or several rings, or from the upper edge of one ear there passes a cord across the forehead to the corresponding part of the other ear, while from either extremity of the cord a bundle of white dogs' teeth hangs down on the side of the neck. The women also have two bags—*[illegible]*—which are much larger than those of the men, and are carried on the back, slung by a band round the forehead. In one of these fruit is brought daily from the plantations into the villages, while in the other the newborn children, or else young pet pigs or puppies, are carried.

J. C. GALTON

(*To be continued.*)

[1] Could these not be used, like similar weapons employed by certain tribes in the heart of Africa, for parrying blows?—J. C. G.

THE MUSEUM OF COMPARATIVE ZOOLOGY, CAMBRIDGE, U.S.[1]

THE Report of the Museum of Comparative Zoology for the past year, which has just reached this country, is of great interest, as it gives us an account of the way in which the supporters of this noble Institution have endeavoured to meet the blow it suffered by the premature death of its founder. The Penikese School of Natural History succumbed, we know, after a faint struggle, but it does not at all appear that the Museum of Comparative Zoology is likely to follow its example. A fund of 260,000 dollars has been raised by public subscription, as a memorial to Agassiz, which is to be devoted to the completion and endowment of the Museum, and the State of Massachusetts has granted a further sum of 50,000 dollars to the like object. As more than the amount, stated to be necessary for the purpose has thus been received, we trust there can be no doubt that the desired object will be attained, and the building finished and its staff endowed according to the plans formed by the late Professor Agassiz.

The general work of the assistants in the Museum of Comparative Zoology during the past year has, we are told, "as usual consisted mainly in preparing materials for exhibition and packing the duplicate collections for exchange." The late Professor Agassiz accumulated, as is well known, enormous masses of specimens of every class in alcohol. But the present Report says:—

"The great difficulty of preserving alcoholic collections, the unpleasant nature, and enormous expense of the work, make it imperative, not only for storage, but still more for exhibition purposes, that they should be restricted to a minimum, and limited as far as possible to those classes where no other mode of preservation is practicable. The constantly increasing facilities of travel, the comparative economy with which fresh specimens can be studied, the superiority of such work with proper appliances to that of the Museum, the daily increasing number of workers who are able, on the sea shore or in the field, to produce results unattainable by Museum study, all go to show that the time has come when large collections must naturally be supplemented by zoological stations. These, when once established at properly selected localities, will enable Museums to dispense with much that is now exceedingly costly. They will become, for certain departments at least, chiefly depositories where the record of work done at the stations—the archives of natural science, so to speak—will be preserved, so that, while their usefulness for the general instruction of the public and of our higher institutions will not be diminished, they must hereafter be useful to the original investigator in a somewhat more limited field."

There can be no doubt of the sagacity of these remarks. They should be well considered by the supporters of the Aquariums now springing up in every direction, which might easily be so arranged as to be useful also as Zoological Stations like that at Naples.

The most important addition made to the collection at Cambridge in 1875, appears to have been that formed by Mr. Alexander Agassiz during his expedition to Peru and Bolivia. This, we are told, contains a "fair representation of the fauna of the high plateau in which Lake Titicaca is situated." A preliminary account of the materials collected is now being published in the "Museum Bulletin." The fishes and reptiles will be described by Mr. Garman, the fossils by Prof. O. A. Derby, the crustacea by Mr. Faxon, the birds and mammals by Mr. Allen, and Mr. Agassiz hopes, himself, to be able to give a short account of the physical geography and geology of the district.

[1] Annual Report of the Trustees of the Museum of Comparative Zoology at Harvard College in Cambridge, together with the Report of the Curator to the Committee of the Museum, for 1875. Boston, 1876.

Thanks to the generosity of the Pacific Mail Steamship Company in passing the baggage free, Mr. Agassiz and his companion took to Peru a large outfit in the way of ropes, dredges, sounding-leads, thermometers for deep-water temperatures, and all the necessary materials for preserving large collections.

Though they were greatly disappointed in the variety of animal life found in the lake of Titicaca and the surrounding shore, they took some very interesting deep-water temperatures (to a depth of 154 fathoms), and completed a preliminary hydrographic sketch of the Lake, which has furnished valuable results, and done much to explain the poverty of its animal life.

The success of the Memorial-fund, of which we have spoken above, will, it is anticipated, enable the principal ideas of the late Professor Agassiz to be accomplished, so soon as the necessary additions to the buildings are completed.

"The foundation will then be laid of an institution in which the claims of college-students, of teachers, of special students, of advanced workers, and of original investigators will be considered, as far as the means and space of the establishment will allow. The public will find in the exhibition-rooms all that is likely to be of interest from the stores of the institution, labelled and arranged so as to be not only instructive, but suggestive.

"Of course time alone will enable us to fill out and complete this plan. We shall be compelled at first to make a very unequal exhibition, but as the blanks become apparent they will be filled.

"From our stores necessary materials for the constantly increasing number of students are to be supplied, and one of the chief duties of the Curator must always be to meet the reasonable demands of those charged with the instruction, by supplying them with ample materials suited to the wants of the different classes engaged in study at the Museum. The special students will have at their command, under proper regulations, in the store and work rooms, of the assistants, the materials of the department in which they are interested.

"To the original investigator the resources of the Museum will always be available, under generous restrictions, with facilities for the publication of investigations made with Museum materials, as far as the means of the institution will allow. On the completion of the additions proposed at present, the Museum will thus consist of several departments of natural history, formerly separated in the University, and now all more or less intimately connected."

In concluding our notice of this report, we shall, we are sure, to be heartily joined by every European naturalist in wishing that these excellent plans of the Director of the Museum of Comparative Zoology may be speedily and efficiently carried out.

THE GREENWICH TIME SIGNAL SYSTEM[1]

II.

We have now to speak of the use made of the time signals beyond the Observatory walls, and will first refer to the hourly currents passing to the Post Office. The original time-distributing apparatus was comparatively simple; afterwards Mr. C. F. Varley devised the chronopher, an elaborate system of switches and relays provided with an accurate clock for opening and closing the switches at the proper times, and forming together a complete automatic system; but on the transfer of the central telegraph station from Telegraph Street to the new building in St. Martin's-le-Grand, it was found necessary to add a second and much larger chronopher, shown in the accompanying drawing. It is to this apparatus that the Greenwich wire is led, and by which the single Greenwich current is simultaneously retransmitted on many different lines. These lines may be considered as divided into four groups :—1, the metropolitan; 2, the short provincial; 3, the medium provincial; and 4, the long provincial. The first group consists of wires passing to points in London; the second of wires passing to towns within a moderate distance of London, as Brighton, &c.; the third of wires passing to greater distances, as Hull, &c.; and the fourth of wires passing to towns or places at a considerable distance, as Belfast,[1] Edinburgh, Guernsey, &c. In each of the four groups the London ends of the several lines are brought into direct connection, each group having its separate battery and relay. On these four relays (the two at the left hand and two in the centre of the six shown) the current from Greenwich acts, and in each relay circuit the local battery current so divides that a portion of it passes out on every wire of the group.

The distribution in London takes place every hour; these wires, being used for time-signal purposes only, remain always connected to the metropolitan relay. To the country, distribution is made twice only on each day, at 10h. A.M. (by the new chronopher), and at 1h. P.M. (by the old chronopher), using the wires of the ordinary telegraphic service, which have, in consequence, to be specially switched into connection with the chronopher. The action at both hours is similar; we shall therefore describe only the 10h. A.M. distribution, which is the more extensive. Shortly before 10h. the chronopher clock (not shown in the sketch) sets in motion the clockwork train shown in the centre of the drawing; this turns over on its axis the flat bar (extending from side to side across the row of upright springs), which pushes the springs backwards, each one out of contact with its corresponding little square stud above. Each spring is in connection with a distant town or telegraph station, the corresponding stud communicating with its particular speaking instrument in the London office. As soon, therefore, as the springs are pushed back, the speaking instruments become all cut off, and the springs (representing distant stations) remain in contact with the long bar. This bar consists of three insulated portions, one for each of the three groups of provincial wires, each having its own battery and relay as before mentioned, and when it comes into contact with the springs in the way described, the distant stations all receive a constant current which serves as warning. On arrival of the Greenwich current at the chronopher the relays act and reverse these battery currents, and these reversals of current indicate at the distant stations the hour of 10h. A.M. precisely. Shortly after 10h. the clock-work train causes the long bar to turn back into its ordinary position, the springs become restored each to its respective stud, bringing the lines all into communication with their several speaking instruments, and the ordinary telegraphic work goes on as before. Of two relays on the right in the drawing, one (by action from the chronopher clock) opens out the relay coils a few seconds only before the hour, and so prevents interruption from accidental currents in the Greenwich line; the other is concerned in the Westminster clock signalling, spoken of further on. The galvanometers are for showing the passage of the various currents of which we have been speaking.

In some cases the current drops a time-ball on the roof of a building, in others a model time-ball is exposed to view in some place accessible to the public; sometimes the current acts on an electric bell, or ordinary galvanometer, and in some cases a gun is fired. The last-mentioned manner of communicating time to the public is one of the most generally useful for ordinary purposes, provided that the observer makes allowance for the rate at which sound

[1] Continued from p. 52.

[1] It is to be remarked that although the signals pass into Ireland, Greenwich time is counted only in Great Britain, Dublin time being counted throughout Ireland. In regulating clocks in Ireland by the Greenwich signals, allowance has therefore to be made for the constant difference between Greenwich time and Dublin time

travels (about four miles in nineteen seconds). Time-guns are thus automatically discharged at 1 P.M. daily at Newcastle, Sunderland, Middlesboro', and Kendal.

The action of the apparatus, both at Greenwich and in the Post Office, is entirely automatic. Still, in the extension of the system, inquiries have sometimes been made as to the degree of exactness of signals received through the chronopher; the accuracy of its transmission has therefore been tested by direct experiment. One of its distributing wires was connected to a wire returning to Greenwich, so that the current leaving the Royal Observatory to act on the chronopher could be directly compared with that received at Greenwich from the chronopher. The currents were made to pass through galvanometers placed side by side, but there was no sensible difference in their indications. It follows, therefore, that entire confidence can be placed in the distribution by the chronopher.

As showing the extent to which demand for the automatic chronopher signals has increased, it may be mentioned that for some years past the *British Postal Guide* has contained a tariff of annual charges for which the telegraph department will supply such signals and maintain the special connecting wires, both in London and the country.

The automatically transmitted signals are scientifically accurate, but a very extensive practical distribution of time is also made daily at 10 A.M. by hand contact. In

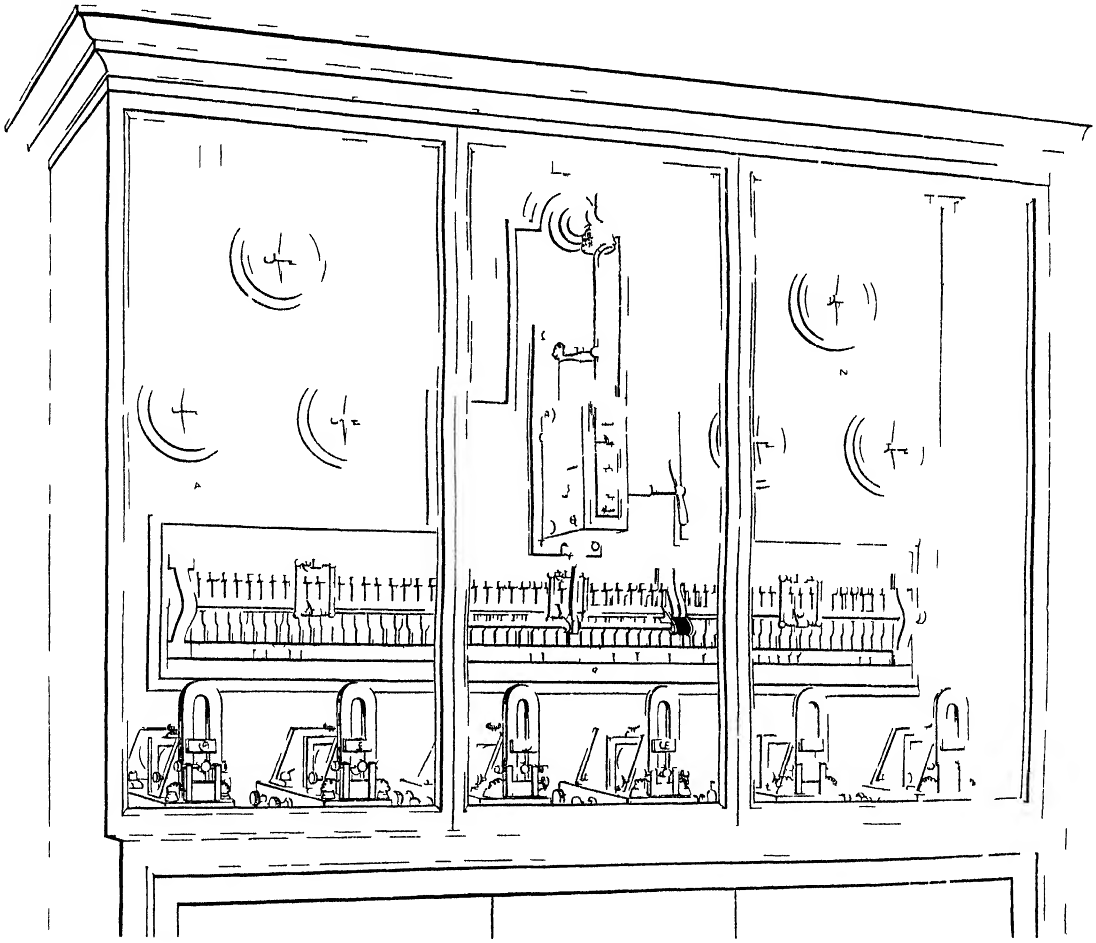

Fig. 2.—New Chronopher (or time distributing apparatus) in the Central Postal Telegraph Office, St. Martin-le-Grand.

the large instrument room of the central telegraph station a "sound" signal is established in connection with the chronopher. When heard at 10 A.M., the clerks, being in readiness, immediately transmit signals by their ordinary speaking instruments to above 600 offices in direct communication with the central station, including those in towns not supplied from the chronopher, the London offices, and the principal London railway termini. At many of these offices the signal is redistributed to others radiating from them, and so practically regulates most of the post office and railway clocks of the country—these in their turn, insensibly as it were, regulating the clocks of the surrounding districts.

Thus, either by the accurate chronopher signal, or by the arrangement spoken of in the preceding paragraph, the 10h. current each morning from Greenwich, through the Post Office telegraph system gives time simultaneously in all parts of the United Kingdom.

One of the chronopher lines in London passes to the clock tower of the Westminster Palace, and hourly signals are received at the clock for its necessary rating and adjustment. It is, however, in no way controlled or mechanically acted upon by the time currents. Practically, the clock requires to be very rarely touched; if change becomes necessary, it is usually made by adding to or removing from the pendulum small auxiliary weights. The clock also completes a galvanic circuit at a certain time daily, and so transmitting a signal, reports

its rate at Greenwich. The statement of the Astronomer Royal in one of his annual Visitation Reports, that the rate of the clock "may be considered certain to much less than one second per week," does not, we believe, overestimate its performance. As regards its absolute variation from true time, we find, according to his last report, that on 83 per cent. of the days of the preceding year its error was below one second. We may mention that the clock has a gravity escapement, that the compensation of the pendulum is entirely metallic and generally similar to that of the Greenwich Sidereal Standard (described in our article on that clock), and that the first blow on the bell at the hour is true clock time, it having been made a condition in the construction of the clock that there should be no loss of time in the first stroke.

So far as regards the work done from one of the wires passing from the Royal Observatory: on the other, terminating at London Bridge, currents also pass from Greenwich hourly, which, with the exception of that at 1 P.M., are placed at the disposal of the South-Eastern Railway Company, who in return give to the Royal Observatory, for two or three minutes daily at 1h., communication between London Bridge and Deal for the purpose of dropping at the latter place a time signal ball belonging to the Admiralty, placed on the old semaphore tower (part of the now abolished Navy Yard). For communication with Deal at 1h. a clock at London Bridge (one of those before spoken of as being controlled from Greenwich) automatically switches the Greenwich wire into communication with a wire on the main line of the South-Eastern Railway. Other special connections are also daily made at Ashford and Deal before the current can pass uninterruptedly from the Observatory to the time-ball; immediately after 1h. the wires are restored to their former positions. To ensure that the ball has fallen properly at 1h., an arrangement exists by which, after its discharge and before it has completed its descent, it makes such momentary changes of the wire connections as cause a "return" signal to pass to Greenwich indicating that it has fallen. This ball was established by the Admiralty to give Greenwich time to shipping in the Downs, and has been in use since the year 1855. It is placed under the superintendence of the Astronomer Royal, who in his annual Visitation Reports gives statistics by which we can judge of its practical working. Examining these reports for the last few years we find, on the average, that about once in two months the ball was not raised on account of high wind, and that about once in six weeks, from accidental telegraphic fault, there was no discharge. An erroneous drop appears to be rare, happening once or so in a year. When such does occur, a black flag is at once hoisted as indication of mistake, and the ball is then dropped at 2h. The efficient working of the ball, thus distant from the Observatory, is considered by the Astronomer Royal to be mainly due to the establishment of the return signal which immediately makes known at Greenwich whether the ball has fallen in the usual way.

Excepting the 1h. current, used as described for the Deal ball, the remaining hourly currents to London Bridge are distributed by Mr. C. V. Walker mainly on the lines of the South-Eastern Railway. For this distribution the clock at London Bridge, already spoken of, switches at different hours different wires into connection with the Greenwich wire, and so passes on the Greenwich current; at some hours it goes to the office of the British Horological Institute in Clerkenwell, for the use of watch and chronometer makers.

It will be seen that the country generally is well served by the system now described, but a useful extension would be made by the establishment of authoritative signals in favourable positions on our coasts, for the purpose of giving to mariners the means of obtaining Greenwich time and approximate sea rates for their chronometers after leaving port. One coast signal only at present exists—the time-ball set up at Deal, as already described. Some few years after its erection, however, it was suggested that a time-signal should be also exhibited every hour at some headland of the southern coast, and after some discussion of localities, the Astronomer Royal proposed a detailed scheme for showing such signals on the Start Point. And more recently the Shipowners' Association of Liverpool made inquiry as to the facilities for exhibiting a similar hourly signal on the Tuskar Rock. Neither of these schemes has yet been carried into execution, but, excepting the question of cost, there seems to be otherwise no difficulty.

It was indicated in an early part of our article that one of the objects of connecting the Greenwich Observatory with the telegraphic system was the possible determination of differences of longitude between Greenwich and other observatories by the exchange of galvanic signals, and since such connection has existed, many important determinations of the kind have been made. We cannot here enter into any detailed description of the different plans that have been from time to time employed in practically carrying out such operations: it will be sufficient to say that the longitudes of the principal British and of some continental observatories have been thus determined. On two occasions Atlantic cables have been employed for fixing the positions of points in America, and more recently (in connection with the Egyptian expedition for observation of the late Transit of Venus) the longitude of Cairo has been by similar means determined. In the latter operation signals were exchanged between the submarine cable stations in Cornwall and Alexandria with perfect success, through one unbroken line of submarine wire. The telegraphic method of determining longitude is one of the most accurate that can be employed.

The connection of the Royal Observatory with the telegraph assists scientific inquiry and even commercial enterprise in various unexpected ways. Capt. Heaviside, R.E., having recently been engaged with some pendulum experiments at the Kew Observatory, it only became necessary to connect the telegraph line at Greenwich to the Sidereal Standard for a few minutes daily, to enable him to receive seconds signals through the Post Office wires, and so refer his observations directly to the Greenwich clock. Also, in the laying of Atlantic cables, an accurate knowledge of Greenwich time being of the greatest importance for the exact navigation of cable ships, Greenwich time has on such occasions been daily passed from the Royal Observatory through the cable itself, as it was being submerged, to the ship.

Our object has been simply to describe the Greenwich system, but we may mention that the plan of telegraphing time, first carried out at Greenwich as part of the daily routine, has since been adopted in other places. In Britain much has been done at the observatories of Liverpool, Edinburgh, and Glasgow, for the dissemination of a knowledge of accurate Greenwich time, both by public clocks and public signals, in the vicinities of those cities. A time-gun is fired daily both at Liverpool and Edinburgh by signal from the observatories of those places. Time-signal systems in connection with observatories are also in operation in various of our colonies, and in places abroad. In the United States of America several very extensive systems have of late years been established, and it has recently been proposed to regulate the clocks of Paris from the Paris Observatory.

The system of employing the ordinary telegraph service of a country for the daily transmission of time in many directions from a fixed observatory shows the benefit that may sometimes ensue from uniting for a special object the powers of two separate institutions of totally different character. The astronomer must for his own particular work obtain from the face of the sky that which, especially in our day, is also so useful to mankind, an accurate

knowledge of the flow of time. This he can, with slight additional trouble, communicate to the external world, although wanting the means of promulgation to any great extent. Telegraphs, on the other hand, exactly supply this want, and can spread abroad in all directions the astronomer's information. Before the transfer of the telegraphs to the State, the successful working of the Greenwich system was due entirely to the existence of amicable arrangements entered into by both parties. But now that the time signal system is, as it were, consolidated, it might well receive greater development. The principal clocks, and those of public institutions, in our large cities and towns, London included, should be more directly regulated than is at present the case by the automatic signals which can be so readily supplied by telegraph, and which might usually be received (as at Westminster) in the clock tower or chamber, for direct comparison with each particular clock. In large towns one wire could be made to serve for many buildings, and the cost for each thus greatly reduced.

The efficient regulation of public clocks in the way mentioned is however a thing entirely for the consideration of the municipal bodies in the various cities and towns concerned. But it is otherwise with the question of the establishment of signals on our coasts for the giving of Greenwich time to outward bound or passing vessels. This is a matter not merely of local, but of national interest; and since the whole subject of the safety of our ships at sea is now under the consideration of the Imperial Legislature, it seems a proper time to direct attention to the usefulness of such coast signals, as tending directly to the improvement of navigation, and thereby contributing in an important degree to the further protection of shipping.

MIGRATION AND HABITS OF THE NORWEGIAN LEMMING

WITH all our recent knowledge of the Northern Fauna, and the ample opportunities of the Scandinavian naturalists, the animal in question still seems to have evaded a thorough scrutiny and complete solution of the why and wherefore of its remarkable migrations. Ten consecutive summers spent in Norway have led Mr. W. Duppa Crotch,[1] in studying the creature, to propound a novel view as to the impetus of its recurrent irruptions. Passing by the traditional lore respecting its sudden appearance in myriads, he discountenances the later informed writers' explanation of hunger, or of the approach of severe weather, being the cause. Even "survival of the fittest, with its cogent subsidiary clause," according to our author, fails to serve as a substantial reason, for, as he observes, none of the travellers survive. His own theory is a very simple one. The bands of migrants always head westward, and at last, in diminished numbers, perish in the sea. In one well authenticated instance (Collet), a ship sailed for fifteen minutes through a swarm, the water being literally alive with them far as the eye could reach. This migratory instinct, Mr. Crotch assumes, is hereditary, their progenitors in the good old times of a colder age having sojourned in a land of plenty, now submerged beneath the Atlantic. ...

completed in one year, as formerly supposed, nor do they, as stated, form processions and cut their way through obstacles; but breeding several times in the season, they gather in batches, and at intervals make a move westward. Their pugnacity, he states, is astonishing, and the approach of any animal, or even the shadow of a cloud, rouses the anger of this small creature like a guinea pig, and they back against a stone or rock uttering shrill defiance. Our author found, in most examples, a bare patch on the rump, due to their rubbing against the said buttress of support when at bay. He wonders why a bare patch, and not a callosity, should not result from this innate, apparently hereditary habit. They cross wide lakes by swimming, but when in the water they are easily frightened and lose all idea of direction, and are inevitably drowned by a slight ruffling of the surface. It seems the reindeer trample them under foot whenever the chance may occur, and other enemies in the shape of hovering rapacious birds and small carnivora thin the numbers considerably as the Lemmings in force drive westward. The writer also called attention to the fact that fossil remains of the Lemming exist in England, as an evidence that the animal had penetrated hither before the island was severed from the continent. The subject altogether is a most interesting and suggestive one, well worthy of the investigation and observation of northern sojourners. Even the recent view of Mr. Crotch, it seems, does not set the whole question at rest. There possibly may be some physical or physiological reason underneath; at all events it is certainly remarkable how a settled westward course is that chosen, calling to mind the similar direction which races of men are assumed to follow.

THE SEYCHELLES ISLANDS

THE Report mentioned below is dated 20th May, 1875, and refers to two visits made to the Islands of the Seychelles group in 1871 and 1874. The islands visited by Mr. Horne were Mahé, Praslin, Silhouette, La Digue, Felicité, Curieuse, Aux Frégates, St. Anne, and Aux Cerfs. The soil, climate, and products of the islands are very similar, so that the remarks made are equally applicable to all of them. The climate is healthy, although the islands are situated almost under the equator, and the Cascade Valley in Mahé, which is at an elevation of 1,500 feet above the sea, is pointed out as being especially delightful. The seasons are two, the warm and wet during the north-west monsoon from October to April, and the comparatively cool and dry season from April to October. The rainfall during the year is about 90 inches, most of which falls during the wet season.

Some of the islands have high mountain peaks, as Mahé, with an elevation of 3,000 feet, and Silhouette with an elevation of 2,500 feet, the highest land in the other islands is less than 1,500 feet. Lagoons often exist between the base of the mountain and the flat sandy beaches which exist in all the islands. In former times crocodiles were abundant in the lagoons, but they have now been extirpated.

The islands are granitic with veins of trap. Coral reefs are abundant but of small size, the largest being on the north-east of Mahé and the north-east end of Praslin. The surface of the islands is mountainous and undulating. Granite boulders are common, and are most numerous near the mountain tops and at the bottom of ravines. The soil is rich and capable of producing any kind of crop peculiar to the tropics. In many places, however, the soil has been washed away, and some of the islands are almost bare rock. There is much uncultivated land, the greater proportion of which is good, but according to Mr. Horne the people are either too lazy or too ...

The chief produce of the islands is cocoa-nut oil and fibre. The plantations of cocoa-nuts are increasing, and many of the young plants are now bearing, which they do when ten or twelve years old. The value of a plantation in full bearing is about three shillings per tree per annum. The oil is extracted by the old primitive mill which has been used in Ceylon and elsewhere for hundreds of years. The fibre is extracted by machinery and will soon

[1] In a paper read before the Linnean Society, May 4.

Report on the Seychelles Islands. Addressed to the Honourable ... J. Horne, Sub-Director, Royal Botanic Gardens ...

form an important item in the exports from the country. The cocoa-nut thrives very well in the Seychelles, and plantations exist from the sandy beaches up the slopes of the mountains to elevations of from 1,000 to 1,500 feet. Tobacco was formerly much cultivated, and was of very fine quality, but the imposition of a tax on tobacco seems to have stopped the cultivation, and Mr. Horne says "the value of the tobacco grown would scarcely suffice to pay the tax, independently of the return which might be expected for their labour." Sugar-cane is cultivated to a small extent to make rum, but although the canes are magnificent, the yield of sugar is small and unremunerative. Cotton also grows remarkably well, but the cultivation has died out since the abolition of slavery, owing to the want of labour during the picking season. The chocolate plant grows freely on waste lands, and its culture is progressing. Vanilla has been planted in several places, and these plantations will shortly be bearing.

Maize and rice are but little cultivated, although in some places two crops of the latter might be obtained each year.

Spices, as cloves, cinnamon, nutmegs, allspice, and pepper thrive well. Clove trees are abundant and attain a height of 40 to 50 feet. The islanders gather the cloves in a reckless and extravagant manner, often felling the trees when the cloves might be reached by a bamboo ladder. The cinnamon is the bitter cinnamon, and is comparatively worthless. The nutmeg and allspice trees were introduced in 1871, and here thrive well. Pepper (*Piper nigrum*) is abundant, climbing over the granite boulders like ivy, and much might be made of it if a few Chinamen or Malays were introduced. Vegetables are very scarce, chiefly from the indolence or indifference of the inhabitants. Manioc and sweet potato are abundant, but yams are very little cultivated. The inhabitants obtain most of their food from the *Colocasia esculenta*. Arrowroot has been planted, and ginger, turmeric, and cardamoms might be easily cultivated. Mr. Horne recommends the rearing of silkworms and the cultivation of coffee. Mulberry-trees grow very readily, and coffee seems formerly to have been cultivated. The only drawback seems to be the want of labour. Pine-apples are abundant but of inferior quality, while oranges are common and excellent. Limes and bigarades are not uncommon, and lime-juice was formerly manufactured to some extent. Other tropical fruits, as anonas, bread-fruit, &c., are common.

During Mr. Horne's two visits he collected about 400 species of plants. About half that number are plants inhabiting all tropical countries, the greater portion of the other half will find congeners in Madagascar, Eastern Tropical Africa, Southern India, the Malay, Polynesian, or Oceanic Islands. The Flora of the Seychelles has no affinity to that of the Mauritius, and Mr. Horne considers that the relations to the Flora of Madagascar will be important from the similarity of geological formation and climate. He also thinks that the Seychelles Flora will have much in common with that of Eastern Tropical Africa. Mr. Horne's specimens have been sent to Kew, and will doubtless be described in the forthcoming Flora of Mauritius and the Seychelles. The Flora seems small, but vegetation is in many places scarce, owing to the occurrence of fires and from the ravages caused by the reckless felling of trees. Much of the ground is covered with dry Palm and Pandanus leaves, which easily take fire. The fire-tracks are readily distinguished by the age of the trees and shrubs now found growing on them.

The palms of the Seychelles are very interesting. The first is the Coco-de-Mer or Double Cocoa-nut. It abounds at Praslin, in a ravine, the highest trees measuring from 80 to 90 feet. The tree growing near the Government House at Port Victoria has flowered for the first time at about its thirty-fourth year. The other native palms of the Seychelles are all *spiny*, viz., a species of *Areca*, *Stevensonia grandifolia*, *Verschaffeltia splendida*, the "*Latanier Haubaum*," and another undescribed species. *Areca rubra* (?), *Hyphæne* sp., and *Latania rubra* or *Borbonica*, have probably been introduced.

Articles, as hats, &c., of almost infinite variety are made from the young leaves of the Coco-de-Mer. The leaves of *Stevensonia* are used for thatch, and the split stems of *Verschaffeltia splendida* make excellent palisades. Ropes are made from the leaves of *Curculigo Sechellarum*, and fibre for cordage is got from *Paritium tiliaceum*. The fibre of *Fourcroya gigantea* (recently introduced) is made into fishing lines. The gum copal of Madagascar is got from *Hymenæa verrucosa*, a rare tree in the Seychelles.

Many useful timber trees are met with. The chief are the following :—

"Capucin," a species of *Siderexylon*.
"Takamaka" (*Calophyllum inophyllum*).
"Bois de Fer," a species of *Dipterocarpeæ*.
"Gayac" (*Afzelia bijuga*).
"Badamier" (*Terminalia badamia*).
"Bois de Natte" (*Imbricaria petiolaris*).
"Bois Marée," a species of *Gomphandra*.
"Bois Rouge" (*Wormia ferruginea*).
"Bois de Table" (*Heriteria littoralis*).
"Sandal," a species of *Rubiaceæ*.
"Bois Montagne" (*Campanospermum Zeylanicum*).
"Cèdre" (*Casuarina equisetifolia*).

Mr. Horne carefully describes the uses of these timber trees.

The ordeal nut of Madagascar (*Tanghinia venenifera*) is met with in the Seychelles. It is a small tree about twenty feet in height, with large clusters of pretty white flowers having a pink centre.

Pigs are fed on the boiled roots of the *Colocasia macrorhiza*; all parts of the plant are poisonous if unboiled.

Pitcher plants, *Pandani*, and species of *Loranthus* are common; Ferns are tolerably numerous, and include the *Cyathea Sechellarum*, *Angiopteris evecta*, &c.

Mr. Horne recommends the Government to purchase the Coco-de-Mer ravine, to prevent the destruction of the trees, and he very properly adds, that "the destruction of the trees would be an outrage on science and a disgrace to civilisation."

Trees seem to be felled quite indiscriminately—a portion of the tree selected, the rest left to rot—so that now good trees are only to be found in the most inaccessible parts of the mountains. We trust that Mr. Horne's report will not be overlooked by the authorities; otherwise we may soon expect to hear that the Seychelles are merely barren rocks and every trace of vegetation gone.

W. R. M'NAB

THE LOAN COLLECTION CONFERENCES

SECTION—PHYSICAL GEOGRAPHY, &c.

Opening Address by the President, John Evans, F.R.S.

In opening the Conferences in connection with this Section of the Loan Exhibition of Scientific Apparatus, it will probably be expected that I should say a few words, if only by way of explanation, of the class of subjects that come within our range, which indeed are neither few nor unimportant. Let me first take the general list of subjects which have on the present occasion been grouped together, and which may be said to constitute our domain. These are Meteorology, Geography, Geology and Mining, Mineralogy, Crystallography, &c. Some of these subjects might no doubt with almost equal propriety have been assigned to other sections. Meteorology might for instance have been classed under the head of Physics and Mineralogy would not have been altogether alien to

the Section of Chemistry. There is, however, so close and intimate a relation between all the various branches of physical research, that it is not only difficult to draw exact boundaries between their provinces, but also to determine to which group any given province shall belong when it becomes necessary to map out the whole field of science into some four or five divisions.

Our province may be regarded in the main as comprising the physical history of the earth—the constitution of its mineral parts and the forms and characters they present when crystallized, the geological succession and nature of its component rocks; the past and present distribution of land and water, and the causes which have led to its modifications; and lastly those meteoric influences which not only affect climate, but are active causes in the carving out of the earth's surface and in the redistribution of the materials of which it is composed. Nor do we only take the purely scientific and theoretical portions of our subjects, but also the application of scientific principles to produce economic results, and to lessen the dangers of those who in the exercise of their calling meet the forces of nature under some of their most destructive aspects.

It is of course only with the apparatus which has been devised for the purpose of carrying on the investigations into the physical history of the earth, and the applications of scientific principles which I have just mentioned, that we are mainly concerned, and not with abstract questions relating to any branches of science. It may, however, be found necessary to enter more or less into such abstract questions if only to show the character of the investigations which have to be pursued, and to elucidate more fully the difficulties with which inquirers have had to contend, or which still have to be conquered. Such questions may also have to be discussed should the history of the gradual development of some of our modern appliances be gone into. Some of the earlier forms of instruments which are now exhibited are indeed of great interest, whether they are regarded in the light of what may be termed milestones on the road of scientific progress, or as memorials of the eminent men by whom they were devised or used. The goniometers of Hauy and Wollaston, the nascent safety-lamp of Davy, the blowpipe of Plattner, the barometer of De Luc and H. B. de Saussure, the thermometer of Gay Lussac, the geological maps of William Smith, the logbooks of Cook, Franklin, and Parry, the instruments and maps of Livingstone, are replete not only with scientific but historical interest.

It is, indeed, as constituting an epoch in the history of scientific discovery, that such a collection as that among which we are now assembled has its highest value and interest. The third quarter of the nineteenth century has just come to its end, and we may venture to compare the advances which have been made during the last twenty-five years not only in our own particular walks of science, but in every branch of it, with the advances which had been made during the previous quarter of a century, the close of which was marked by the first Great Exhibition held in London. Great as had been the progress in scientific knowledge and in the application of scientific principles during that second quarter of the century, and favourably as it contrasted with the by no means despicable attainments of the previous quarter, the advances made during the last twenty-five years both in our knowledge of the principles of the great forces of nature and in the accuracy and delicacy of our instruments for their investigation are such that the present generation has at least no cause to be ashamed of them. Possibly when another quarter of a century has elapsed, those who come after us and those among us who survive as labourers in the field of science, may look back upon some of the processes now in vogue as antiquated, and may even feel surprise at our having been upon the verge of some great discoveries and yet having failed to make them; but I venture to hope that the names of many of those living investigators which we find recorded in the Catalogue of this Exhibition may not only then, but even in after ages, be looked upon with reverence and esteem.

We must, however, turn to the consideration of the branches of science comprised under this Section, and in directing your attention to some of the objects which appear to me of more than common interest, I shall venture an occasional observation on some matters which appear to be well fitted for discussion at an international conference such as the present.

In regard to meteorological instruments we have not only isolated specimens but sets of instruments as supplied to meteorological stations, and to the royal and merchant ships of this country. With the exception of Russia, however, the means of comparison with other countries are, I believe, wanting. It will be for the representatives of other countries to see whether some useful hints may not be derived from the experience of British meteorologists as embodied in these selections of instruments.

Mr. R. H. Scott in the "Handbook to the Collection" has given so excellent an account of the nature of the meteorological instruments here exhibited that I need add but little to it, especially as he will be good enough to make a communication upon them.

Taking the principal forms it will be seen that among the barometers there are more than one exhibited which are of historical interest, while numerous examples of modern improvements in mercurial barometers are shown, of which perhaps those intended to facilitate their use and increase their accuracy when employed by travellers by land and by sea, are the most noteworthy. For ordinary use, however, that comparatively recent form of barometer, the Aneroid, seems likely to compete with the older form, and the precision of mechanism which some of them exhibit is marvellous. That extreme delicacy, however, has its disadvantages, and for trustworthy observations the actual weighing of the atmosphere by the column of mercury will long be preferred.

The principal features of the thermometers are their accuracy and sensitiveness. It might be worth while to consider whether any means could be devised for facilitating the adoption of a uniform scale of notation. It will, however, be a difficult matter to supersede the scale of Fahrenheit in this country, where it seems to have taken so deep a hold. The more general introduction of instruments marked with both Fahrenheit's and the centigrade scale might assist the adoption of the latter, but the smaller unit of heat on the former scale gives it practically some advantage.

Of anemometers, both for meteorological and mining purposes, a large number will have been seen, some of them furnished with means of recording both the direction and strength of the currents. Of several of these, details will be given at this Conference.

With respect to rain-gauges but little need be said, unless it be to call attention to the system, which, thanks to Mr. G. J. Symons, is now so universal in this country, viz., for observers who make only one daily entry of the rainfall, to take their observation at 9 A.M. and to enter the amount of rain to the preceding day. The late Meteorological Congress has no doubt discussed this and other points of international interest.

Of hygrometers, both ancient and modern forms are exhibited, the hair hygrometer still holding its own among those of the indirect class, notwithstanding the influences of modern civilisation. One cannot but be touched by the pathetic note of the Geneva Association for constructing scientific instruments. "The most isolated hamlets have now to be searched in order to obtain hair uncombed," and therefore fit for these instruments.

It is perhaps in the self-recording instruments that the greatest advance made during the last quarter of a century will be observed. The extended use of electricity and

photography has aided in this as much as in other departments of science, and the daily weather charts now issued in this country would have been impossibilities but a few years ago.

The automatic light-registering apparatus of Prof. Roscoe will it is hoped be the subject of a communication to the Conferences of this Section; but this and several other recording instruments are fully described in the Catalogue, as are also various interesting charts illustrative of meteorological influences on mortality and disease. The relation which has been found to subsist between colliery explosions and the state of the weather will form the subject of some observations to the Conference by Mr. Galloway.

There is only one other point in connection with meteorology on which I will say a few words: that of evaporation. Two or three forms of atmometers or evaporimeters are exhibited, some of them intended to determine the quantity of water evaporated from different kinds of soil, but no form of instrument is, I believe, in the collection which will serve to ascertain the proportion of the rainfall which percolates to any given depth through a porous soil. When it is considered how large a proportion of the surface of the globe consists of such soils and how important is the question of the supply of spring-water to our wells and rivers, it will perhaps be a matter of surprise that more attention has not been directed to the subject. It is not, however, one on which to enter at length in an introductory address, though I hope to recur to it in the course of the afternoon.

The second subject comprised within our Section is that of Geography, which, thanks to our distinguished African, Asiatic, Arctic, and marine explorers is at the present time attracting so much public attention. Many of the instruments exhibited have much of historical and personal interest, among which may be reckoned the series of instruments belonging to the Ordnance Survey, some of them—like Ramsden's theodolites exhibiting to what a point the construction of such instruments had advanced even at the end of the last century. What, however, will attract universal attention are the deep sea sounding appliances, which have so greatly conduced to the success of the *Challenger* Expedition, and the great extension of our knowledge of the character of the deep-sea deposits of modern times, which throw so important a light on the history of many earlier geological formations.

This interest is much enhanced by the satisfaction we must all feel in again welcoming among us the distinguished naturalist who has had the scientific charge of that expedition. Let us all hope and trust that the gallant captain of the expedition during the first portion of its voyage, may in like manner return in due course with his present comrades from his still more adventurous exploration of the Arctic regions, crowned with the success which his efforts so well deserve.

Among the deep-sea sounding apparatus, that most ingenious invention of Dr. Siemens, the bathometer, which has been exhibited and described in another Section, will, no doubt, have attracted your attention, of which many of the levelling and surveying instruments exhibited in this Section are also so well worthy.

The collection of maps requires but little comment. The survey of Palestine, the charts of the Arctic Regions, the survey maps of India, and the beautifully executed maps sent from foreign countries cannot escape attention. In connection with recent explorations the remarkable section across Southern Africa, executed by Lieut. Cameron during the perilous journey from which he has just returned, will, I hope, be the subject of comment in these Conferences by its distinguished author. Nor should the ancient maps of the sources of the Nile exhibited by the Royal Geographical Society be left unnoticed. It might be a subject for discussion whether some more uniform system of symbols for use on maps might be adopted for general use among all nations.

In the department of Geology and Mining, it may be observed that the instruments of the pure geologist are but few and comparatively simple. We have, however, before us a most valuable collection of the geological maps of various countries, showing how vast has been the advance of our knowledge in this field during the last quarter of a century. The principles on which the geological survey of this country has been directed will be illustrated by its present accomplished chief, Prof. Ramsay, and we shall, I hope, hear something as to the surveys now going on in other countries. It would be a matter well worthy of consideration in an assembly of this kind, whether for the general geological features of a country, some international system of colouring could not be agreed upon, and in future be adopted. For more detailed maps entering minutely into the subdivisions of formations, such a system might be difficult to devise, much more to carry out; but for the principal formations there ought surely to be no great difficulty. Already, for something like two centuries, the colours in heraldry have been represented all over Europe by a conventional system of vertical, horizontal, oblique, and other lines, and science would not suffer if on this occasion she walked in the wake of vanity.

Among the appliances of the geologist must be reckoned his palæontological and mineralogical collections which, however, are, except in special instances, too bulky for an exhibition of this kind. Some are, however, here, and among them, a magnificent series of rocks, minerals, and fossils from Russia, and the fossil vegetable remains, both from the Continent and England, well deserve notice. We shall, I hope, hear from Baron von Ettingshausen how the genetic descent of much of the flora of the present day may be traced back into Tertiary times, and Mr. J. S. Gardner will have something to say on the same subject.

The sub-wealden boring, which has attained a depth of 1,900 feet, without, however, reaching any rocks of Palæozoic age, will also form a subject of comment. The process of the Diamond Rock Boring Company by which it has been carried on, has not only the advantage of being more expeditious than the older process, but has the great merit of producing such excellent cores as those which can be seen at the end of this gallery.

The ingenious machines of Mr. Sorby, illustrative of various geological phenomena, and the original drawings of Buckland and Phillips will also attract attention.

The specimens illustrative of M. Daubrée's experiments on the artificial formation of metamorphic and other rocks, and the minerals formed within the historical period by means of hot springs, will be rendered doubly attractive by the account to be given of them by that eminent geologist.

As objects of historical interest, however, the collections illustrative of the development of Davy's great invention of the safety-lamp, are perhaps unrivalled in this department. Among mining appliances and models, some few will form the subject of communications to the Conferences.

In the remaining department of this Section, that of Mineralogy and Crystallography, there is much of historical as well as scientific value. The improvements in the microscope, the polariscope, and the goniometer, have done much to advance these branches of science during the last quarter of a century, while the application of photography to the reproduction of the images observed in the microscope has most efficiently aided in bringing the results of single observers within the reach of all.

The models and diagrams illustrative of the different systems of crystallography and the various forms of crystals are remarkably excellent and complete, and some questions in connection with the properties of certain

forms of crystals, and the method of notation best adapted for international use, will probably be discussed in the Conference.

I have thus briefly touched upon some of the salient points which occur to the mind when taking a cursory view of an Exhibition such as the present. In doing so I have no doubt passed over many instruments and appliances of even greater importance than those which I have thus succinctly mentioned, and have probably left untouched many topics of the highest interest. Among the subjects, however, which will be discussed on each day of our Conferences there will, I hope, be a sufficient variety to give occasion for any one to call attention to any special features of novelty in the collection. What I have ventured to say must be regarded as merely a short introduction to communications of far greater value, from which I will no longer detain you.

SECTION BIOLOGY

Opening Address by the President, Prof J. Burdon Sanderson, M.D., LL.D., F.R.S.

It having been made a part of the duty of the chairman of each of the sections into which this Exhibition is divided to deliver an opening address, I had no difficulty in selecting a subject. I propose to place before you a short and very elementary account, addressed rather to those who are not specially acquainted with biology than to those who are devoted to the science, in which I shall give you a description of a few of the methods which are used in biological investigation, particularly with reference to the measurement and illustration of vital phenomena. You are aware that the Committee, in order to render these conferences as useful as possible, have thought it desirable that we should devote our attention chiefly to those subjects of which the instruments in the collection contribute the best examples.

Now these subjects are, first, the methods of registering and measuring the movements of plants and animals; secondly, the methods of investigating the eye as a physical instrument; and thirdly, the methods of preparing the tissues of plants and animals for microscopical examination. Of these several subjects it is proposed we should to-day concern ourselves chiefly with the first. I will therefore begin by endeavouring to illustrate to you some of the simplest methods of physiological measurement, particularly with reference to the *time* occupied in the phenomena of life, leaving the description of more complicated apparatus to Prof. Donders, who will address you on Monday, and to my friend, Prof. Marey, who is with you now, and who will give you an account of some of the beautiful instruments which he has contrived for this purpose.

The study of the life of plants and animals is in a very large measure an affair of measurement. To begin, let me observe that the *scientific* study of nature, as contrasted with that contemplation of natural objects which many people associate with the meaning of the word "naturalist," consists in comparing what is unknown with what is known. Whatever may be the object of our study—whether it be a country, a race, a plant, or an animal, it makes no difference in this respect, that the process in each of these cases is a process of comparison, a process in which we compare the object studied in respect of such of its features as interest us, with some known standard, and the completeness of our knowledge is to be judged of in the first place by the certainty of the standard which we use; and secondly, the accuracy of the modes of comparison which we employ. Now, when you think of it, comparison with a standard is simply another expression for measurement; and what I wish to impress is, that in biology, comparison with standards is quite as essential as it is in physics and in chemistry. Those of you who have attended the conferences on those subjects will have seen that a very large proportion of the work of the physical investigator consists in comparison with standards. From his work, our work, however, differs in this respect, that whereas he is very much engaged in establishing his own standards and in establishing the relations between one standard and another, we accept his standards as already established, and are content to use them as our starting-point in the investigation of the phenomena which concern us.

Now I wish to illustrate this by examples. The first objects which strike the eye on entering this collection—the collection in the next room—are certainly the microscopes. But you will say, surely the microscope cannot be regarded as an instrument of measurement. In so far as it is an instrument of research and not merely a pastime, it is emphatically an instrument of measurement, and I will endeavour to illustrate this by referring to one of the commonest objects of microscopic study, namely, the blood of a mammalian animal. Now as regards the blood I will assume that everybody knows that the blood is a fluid mass, in which solid particles float. With reference to the form of those particles, all that we see under the microscope is merely a circular outline. If we wish to find out what form that represents we must use methods which are really methods of measurement. By the successive application of such methods we learn that this apparently circular form really corresponds to a disc of peculiar bi-concave shape. But I will not dwell more upon the application of measurement to the form of the corpuscles, but proceed at once to a subject that can be illustrated by an instrument before you for ascertaining the *number* of the corpuscles. It will be obvious to you—even to those who are not acquainted with physiology and pathology that the question of the proportion of corpuscles which are contained in the blood must be a matter of very great importance to determine. It has been long known that the colouring matter which is contained in the corpuscles is the most important agent in the most important vital processes of the body, because it is by means of it that oxygen, which is necessary to the life of every tissue is conveyed from the respiratory organs to the tissues. This being the case, it is evidently of very great importance both to the pathologist and to the man who interests himself in investigating the processes of nature, to be able to determine accurately what proportion of corpuscles the blood contains. Well, there are chemical methods of doing this. We can do it by determining how much iron the blood contains, because we know that the proportion of iron in the corpuscles is always nearly the same, and by determining the quantity of iron chemically, we can find out how many corpuscles there are in a certain amount of blood. But this is a long process, requiring first the employment of a considerable quantity of blood, and secondly, difficult chemical manipulations and a long time. Now by a method which has been very recently introduced, we have the means of applying the microscope even to a single drop of blood, to a drop such as one could obtain by pricking one's finger at any moment, or could take, in this way, from any patient in whom it might be desirable to ascertain the condition of the blood as regards the number of its solid particles.

The method consists in this. In order that you may understand it I will ask you to fix your attention upon this cube which I draw on the board. Suppose this cube is not of the size actually represented, but that it is a cube of one millimetre, *i.e.*, the $\frac{1}{25}$ part of an inch. How many blood corpuscles do you suppose are contained in a cube of that size? Such a cube we know to contain in normal blood about 5,000,000 corpuscles. Supposing we had a method by which we could count those 5,000,000 particles it is obvious that the task would be endless, and even if we were to take a cube $\frac{1}{125}$ part of that size, namely, a

ment. We have two electrical keys, one at the further end intended for making what is called the signal, and one here for breaking, which is placed close to the person who is to be experimented upon. Mr. Page, at any moment he likes, will act upon me by sending an induction flash through my tongue. I shall arrange the electrodes so that they shall be against the tip of my tongue, and at the moment I feel that flash I shall place my finger on the key. Then the clockwork being in motion at the same time, we shall see by the length of the depression in the tracing the duration of the process. If we take different sorts of signals, or if the person to be experimented upon is in different conditions, the time will be very different. Thus we may compare the result which will be produced when I am attending and expecting the signal with the result which will be produced when I am not attending or expecting the signal; or, on the other hand, I may compare those results with that which will be produced when I am expecting it, but Mr. Page, instead of giving it at the time I expect it gives it me at a different time; in that case the time occupied would be longer than in either of the other two cases. A great variety of different cases can be investigated in this way in which we measure the total period occupied in the reflex. The arrangement is perfectly simple. You see when Mr. Page presses on his key, which is the signal key, that a lever is set in vibration and makes a tracing, and at the same moment the voltaic current is made and the coil is acted upon inductively; the result is that an induction flash passes through my tongue which I feel, and the moment I feel it I break the current. Consequently the time between the moment at which Mr. Page makes the current by closing his key and the moment at which I break the current by placing my finger on my key, gives us precisely the time which is occupied by the reflex process. We will make two experiments, first, with the signal expected, and then unexpected: that is, in the one case I shall be on the *qui vive*, and on the other I shall not be so. (The experiments were made accordingly.) We shall now repeat the process, so that instead of my receiving the information of the making of the current by means of the excitation of my tongue, the signal shall consist in my hearing the sound of an electrical bell. In that case we shall find that, although the signal will come in exactly the same way, practically the time occupied will be very considerably longer, showing that a signal received by sound takes longer in producing its effect than one in which the signal is felt by the tongue.

In order to make all this perfectly plain I shall hand round this tracing. You will see there several experiments made with expected and unexpected signals, which show the different results obtained in the two cases.

The next question which arises, and with that I must conclude what I have to say just now, is this:—You will readily see that the exact measurement of time depends upon the rate at which this clockwork happens to be going. I happen to know that it makes twenty revolutions per second. But suppose I do not know that. In fact one would not trust to the accuracy of clockwork for such a purpose. How should I then be able to measure the duration of time so exceedingly short as the one which now concerns us? In order to do this we always come back to a physical standard, to a standard of absolute invariability which we can depend upon as being true. For this purpose we use a tuning-fork which produces vibrations, the rate of which we know, because we know the tone which the tuning-fork produces, and the arrangement which is always used for this purpose is the one shown here. We have turned off the voltaic current we used for signalling, and turned it on the tuning-fork. There are two electro-magnets on either side of the tuning-fork which react upon it, so that the moment you close the current the fork is thrown into vibration and produces its own characteristic note. All that we have to do is, during the time we are making our record, to bring this tuning-fork, which is now in vibration, into such a position that this little brass pointer shall make a tracing against the paper. If you look at the tracing I have sent round you will find there are tracings on it of a fork, which vibrates at the rate of 100 per second, consequently you have nothing to do but to translate the tracings which you have made and which correspond to the duration of the mental process which you have been investigating, into vibrations of the tuning-fork, and you get an exact measurement of the total duration of the process. While I have been doing this you hear the tuning-fork is in vibration, and Mr. Page has made the tracings. After it is varnished it will be sent round and you will see the tracing made by the fork over the traces corresponding to the different experiments we made just now.

I may observe that although the experiments made on that paper were made with myself, you find that the period occupied by the reflex is considerably longer than in the other which I sent round previously. But that one may very easily explain from the abnormal conditions under which the experiment has been made as regards myself.

I intended to go on from this subject to another mode of investigation, namely, to the very beautiful instruments which have been lately introduced for the purpose of measuring the finest differences of bulk in different organs, as for example, in the human arm, by which you can ascertain the condition of the circulation precisely by a very exact registering-measurement of the bulk of the arm;[1] but as there are several other gentlemen now ready to address you, I will defer that till this afternoon. I will now conclude what I have to say by asking you to listen to Dr. Hooker.

SCIENCE IN GERMANY

(From a German Correspondent.)

HERR v. OBERMAYER has recently communicated a memoir to the Vienna Academy on the relation of the coefficient of internal friction of gases to the temperature. If we accept for the coefficient of friction μ at t° C., the formula—

$$\mu = \mu_0 (1 + at)^n$$

where a is the coefficient of expansion of the gas, taken as basis of the calculation, then the experiments of Obermayer give the following results:—

For Air	n	0·76
Hydrogen	n	0·70
Oxygen	n	0·80
Carbonic oxide	$n =$	0·74
Ethylene	n	0·96
Nitrogen	$n =$	0·74
Protoxide of nitrogen	$n =$	0·93
Carbonic acid	n	0·94
Ethyl chloride	n	0·98

The coefficient of friction of the permanent gases is, according to these experiments, approximately proportional to the $\frac{4}{5}$-power of that of the coercible gases, and to the 1-power of the absolute temperature.

For temperatures between 150° and 300° C., air gave the same values of n as between the lower temperatures −21°·5 and 53°·5. In the case of carbonic acid a slow decrease of the exponent n with the temperature was perceptible from the experiments. W.

NOTES

ON Tuesday a visit was paid to the *Challenger* at Sheerness by several Fellows of the Royal Society, foreign men of Science, who are in London in connection with the Loan Collection

[1] The apparatus was fully described subsequently by Mr. Gaskell.

Conferences, and representatives of the Science and Art Department. Among those who made up the party were Lord Clarence Paget, Sir Henry Cole, Mr. Norman Macleod, Majors Donnelly and Festing, Mr. E. J. Reed, M.P., Professors Allman and Crum-Brown, Mr. Norman Lockyer, Professor Eccher, Baron von Wrangell, Dr. Biedermann, and others. Luncheon was served in the Ward-room, but as there was not sufficient accommodation for all the visitors many left by special train for Chatham, where luncheon had been provided in the Engineers' Mess-room. Invitations to visit the *Challenger* have been sent by the Admiralty to all the English and foreign members the Kensington Loan Apparatus Committee, many of whom have accepted them. The *Challenger* will be open to inspection to-morrow. The ship lies at present in the very spot she left when she set out on her cruise three and a half years ago, and to-day she is to be swung for the adjustment of her compasses and the taking of magnetic observations. It is thought that ten or twelve days will elapse before all the stores can be taken out to enable her to pay off.

FROM the official list of visitors to the Loan Collection during last week, which we give below, it will be seen that full advantage is being taken of the opportunity afforded :—

DR. DONDERS, of Utrecht, and Prof. van Beneden, of Louvain, are two of the latest arrivals in connection with the Loan Collection Conferences.

IT is proposed to hold an International Convention of Archæologists, at Philadelphia during the Centennial, and in connection with the Centennial Exposition, for the purpose of promoting acquaintance and increasing the means of information in American Archæology and Ethnology. The State Archæological Society of Ohio will provide rooms for the Convention, and the first meeting will be held in the Ohio Building, at 2 o'clock, P.M., Sept. 4, 1876. The American Association for the Advancement of Science, meets at Buffalo, N. Y., Aug. 23, at which time a Subsection of Anthropology will be formed. The Convention has been appointed near the close of the session of the Association in order that those who desire may conveniently attend both meetings. Large collections, in Ethnology and Archæology, from the Smithsonian Institution, the State Society of Ohio, and other public and private sources, will be on exhibition, and will furnish a great incentive for Archæologists to visit the Exposition. The meeting of this Convention at Philadelphia, must be regarded on that account as very opportune, and a large attendance is expected. Addresses from prominent anthropologists will be delivered, and it is hoped that a great impetus to investigations in America will be gained. Archæologists who purpose to attend are requested to bring any articles or illustrations which they may have, as the opportunity for a temporary exhibition will be given. The Chairman of the Ohio Committee is the Rev. S. D. Peet, of Ashtabula, O. European men of science who intend to be present at the Buffalo meeting of the American Association, should write to Prof. F. W. Putnam, Salem, Mass., who might be able to make arrangements, by which their expenses would be kept down.

IN connection with the great International Exhibition at Philadelphia, it is interesting to note that that city is one of the healthiest in the world, so far as the death-rate is a test. In 1874, according to an official circular just issued, with a population of 775,000, the death-rate was only 19·3 per thousand. This very favourable result is largely due to the abundant and cheap water-supply, and to the opportunities given, even to the poorest citizens, for the enjoyment of pure country air in the great Fairmount Park, which contains 2,991 acres. The most powerful influence of all, however, is the absence of that overcrowding of the population, which is the most fruitful source of sickness and death in many quarters of nearly all other large cities. This will be more clearly comprehended when it is remembered that the 817,488 inhabitants of Philadelphia are spread over an area of 129½ square miles, which are traversed by more than one thousand miles of streets and roads. The climate of Philadelphia is also, on the whole, a favourable one, although presenting many of the peculiarities common to inland localities. The mean annual temperature of the last ten years is 53·73° Fahrenheit; the average annual rain-fall is about forty-five inches.

THE Conversazione of the President of the Institution of Civil Engineers takes place to-night in the South Kensington Museum itself, instead of in the Galleries devoted to the Scientific Apparatus Exhibition, as was at first intimated.

WE are informed that the new Zoological Gardens of Calcutta will be opened on the 6th of this month, and that Mr. J. C. Parker has been appointed temporary Curator of the establishment. There is a fine show of Indian Ruminants and other ordinary Indian animals; a splendid pair of the Himalayan Bears (*Ursus tibitanus*), and likewise examples of the other Indian species, *Ursus labiatus*, *U. malayanus*, and *U. isabellinus*. Among the rarities is a cage full of the Indian Tupaia (*Tupaia ellioti*), a curious insectivorous form, of which the Zoological Society of London had living examples not long since.

THE *Pandora* left Portsmouth on Saturday on her voyage to the Arctic Regions. One of her main objects is to take out letters, papers, &c., for the officers and crews of the *Alert* and *Discovery*: these will be deposited in certain dépôts on the chance of Capt. Nares being able to communicate with the entrance to Smith's Sound. The *Pandora* takes out a very considerable number of letters and packets of various kinds, and not the least interesting news to Capt. Nares will be that of the successful conclusion of the *Challenger* Expedition. It is generally understood that, after depositing his mail, Capt. Young will make another attempt to push his ship through Peel Straits, or Bellot Straits, and Franklin Channel, and so on into Behring Straits, and thus be the first to make the North-west Passage.

IT is encouraging to find our legislators and "leaders of industry" enlightened enough to realise and plainly state the condition of this country with regard to scientific education. The place which this country at present holds in the matter of scientific industry, as contrasted with Continental countries and with America, has been frequently referred to of late both by public men and in these columns. The case was again briefly but pointedly stated by Mr. Samuel Morley, M.P., on Monday, at the Annual Meeting of the Artisans' Institute. "It was," he said, "essential that our sons of toil should become humble disciples of science if England was to keep pace with foreign nations in the excellence of her manufactures. The competition of industry was rapidly becoming a competition of intellect; and Belgium, Germany, and America were fast treading upon our heels in the quality of their manufactures. Seeing that at no period for thirty years had there been so widespread a depression in trade as at present, he thought the great importance of imparting scientific instruction, with a view to the maintenance of our position, would be sufficiently obvious to all. Unless this was brought to bear upon our manufactures, the situation of this

country would be one of great peril, and he sincerely hoped that the advantages offered to the working classes would be thoroughly appreciated by those whom the organisation was intended to benefit." We hope that sentiments like these will have due weight in the framing of our Education Codes.

WE are glad to hear that the Duke of Cleveland has directed the Shropshire meteorite to be placed at the disposal of the authorities of the British Museum.

IN October next, we learn from the *Western Daily Press*, the Bristol University College will be an accomplished fact. Professors of Chemistry and of Modern History, and Literature are to be appointed for the opening of the first session and Lectures delivered on the following subjects:—Mathematics and Applied Mechanics, Experimental Physics, Political Economy, and Classical History and Literature. It is gratifying to find that public spirit in Bristol has not only not allowed a great opportunity to pass, but has brought the College into existence, as a working institution, with praiseworthy rapidity. The council has appointed Mr. F. N. Budd as chairman, Mr. W. Proctor Baker as treasurer, and Mr. Edward Stock, secretary.

B. C. DUMORTIER'S "Hepaticæ Europæ," published by C. Muquardt of Brussels, is the only work which gives a complete account of the Hepaticæ or Liverworts of Europe, and embraces the work of more than fifty years of a veteran botanist. For a limited period, until July 1, the work is offered at a reduced price of 5fr., after which the published price will be 8fr. It is illustrated with four coloured plates.

BY authority of M. Waddington, the older pupils of the National School of Agriculture, established at Grignon, in France, left, on May 25, for the Netherlands, where, with their professors, they are to make an agricultural tour which is to last for three months. It is stated that they will come to England next year. Grignon was the first agricultural school established in France, and was purchased by the Government many years ago. The course of studies is for three years.

DR LEFORRAIN, a *licencié* in natural science, has just organised a series of scientific excursions in the vicinity of Paris. They are to take place each Sunday during the months of June, July, and August. The excursionists will receive practical instruction in geology, botany, and entomology, by competent teachers.

ON Monday June 26, an extraordinary session of the French Botanical Society will be held at Lyons. A number of botanists from Belgium and Switzerland will join the Society, and an important botanical exploration will be made. English botanists will be very heartily received. Particulars may be obtained by directing letters to the General Secretary, 84, rue de Grenelle, St. Germain, Paris.

THE eighth session of the International Anthropological and Archæological Society will be held at Buda Pesth, under the presidency of M. Francois Pulsky, General Inspector of the Public Libraries in Hungary. The General Secretary of the Buda-Pesth Congress is M. Florian Romer. An English committee will be appointed.

WE are glad to see that a second edition of Mr. W. N. Hartley's "Air and its Relations to Life," has been published by Messrs. Longman and Co. In this edition Prof. Tyndall's recent experiments are described.

WE have received Dr. C. Bruhn's monthly reports of the meteorological observations made at twenty-four stations in Saxony during 1875. To the reports which briefly summarise the results for each month is appended an interesting *résumé*, pointing attention to the more striking features of the weather during the year, and comparing these with the results of previous years' observations, and giving the annual means and extremes of all the meteorological elements at each station, together with the dates of occurrence of several interesting phenomena, such as the day of heaviest rainfall, of greatest dryness of the air, and the latest and earliest frost and snow.

IN the *Bulletin International* of the Paris Observatory of May 17 to 19, there appears an important paper by M. Belgrand, on the means of protecting Paris from the inundations of the Seine. The great flood of March 17 last marked 107½ feet on the river-gauge at the bridge of Tournelle, which is three feet less than the height to which the great flood of Jan. 3, 1802, rose, and 7½ feet less than that of Feb. 27, 1658, the greatest flood on record. With a view of protecting the parts of the city liable to suffer from such floods, M. Belgrand proposes to prolong the main drains and the embankments down the river as far as the fortifications, to isolate them completely from the river, and to keep them, by means of machinery, at their normal level. Further, to prevent the flooding of cellars, he proposes a system of drainage at a lower level than that of the cellars liable to be flooded, and having no communication with the river and the main drains, these drains to be kept at the proper level by centrifugal pumps and turbines driven by the water of the city.

WE have received the first part of the first vol. of a "Handbuch der Paleontologie," by Profs. Schimper and Zittel. It is published at Munich, by R. Oldenbourg.

MR. W. DITTMAR has just published (Edmonston and Douglas) a collection of useful Tables as an Appendix to his "Manual of Qualitative Chemical Analysis," which we recently noticed.

"ESSAY on the Use of the Spleen, with an Episode of the Spleen's Marriage, a Physiological Love-story," is the title of rather an original little work just published by Dr. Patrick Black (Smith, Elder, and Co.).

AS Supplement 47 to Petermann's *Mittheilungen*, has been published an account of Herr G. A. Haggenmacher's Travels in Somali Land. The author gives a systematic account of his observations in this region of Africa, under the headings of Narrative of the Journey, Physical Geography, Ethnography and Ethnology, Agriculture and Cattle-breeding, Industries and Trade, and a History of the Somalis.

THE latest additions to the Royal Westminster Aquarium include the following:—Hawksbill Turtles (*Caretta imbricata*), from the West Indies; Picked Dogfish (*Acanthias vulgaris*), and Lesser Spotted Dogfish (*Scyllium canicula*), presented by the Yarmouth Aquarium Society; Armed Bullheads (*Agonus cataphractus*), Greater Pipefish (*Syngnathus acus*), Sea Horses (*Hippocampus ramulosus* et *brevirostris*), Venus's Ear-shells (*Haliotis tuberculata*), from Guernsey; Sea Mice (*Aphrodita aculeata*), Purple Urchins (*Echinus lividus*), Sun Starfish (*Solaster papposa*), Mediterranean Corals (*Balanophyllia verrucaria*), Venus's Flower-basket Sponge (*Euplectella aspergillum*), from the island of Zebu, Collected and presented by Capt. W. Chimmo, R.N.

THE additions to the Zoological Society's Gardens during the past week include a Silver Pheasant (*Euplocamus nycthemerus*) from China, presented by Mr. W. Miles; a Common Barn Owl (*Strix flammea*), European, presented by Mrs. Knight; a Blue-faced Amazon (*Chrysotis amazonica*) from South America, presented by Miss M. Jukes; a Silky Marmoset (*Midas rosalia*), a Huanaco (*Lama huanacos*), an Azara's Fox (*Canis azaræ*), three Chinchillas (*Chinchilla lanigera*) from South America, deposited.

SCIENTIFIC SERIALS

THE *Journal of Mental Science*, April, 1876.—Reflex, automatic, and unconscious cerebration, a history and a criticism, by Thomas Laycock, M.D., is continued and completed in this number. The paper is very interesting. Dr. Laycock takes great pains, and is, we think, successful in making good his claim to priority over Dr. Carpenter in certain views of an advanced nature, which, if they are not already, will soon be entirely absorbed in others much more advanced.—Dr. John M. Diarmid writes in high praise of morphia in the treatment of insanity, when administered subcutaneously.—Dr. Daniel Hack Tuke gives an historical sketch of the past asylum movement in the United States, doing full justice to the enlightenment and humanity of American physicians, while recording the outstanding difference between them and their English brethren in the principle and practice of non-restraint.—A modest but suggestive paper on the use of analogy in the study and treatment of mental disease, is contributed by Dr. J. R. Gasquet.—Dr. P. Maury Deas describes a visit to the Insane Colony at Gheel, where the accumulating experience of a thousand years has produced an instinctive aptitude to manage the insane worth more in practice than the best of our consciously-formed systems.—Dr. Isaac makes some interesting observations on general paralysis.—"Arthur Schopenhauer: his Life and his Philosophy," by Helen Zimmern, is reviewed in a manner worthy the book and its subject.—The *Journal* contains other reviews, clinical notes and cases, news, &c.

Zeitschrift der Oesterreichischen Gesellschaft fur Meteorologie, Feb. 1.—In this number appears the first part of a paper by Dr. W. Koppen, on the yearly periods of probability of rain in the northern hemisphere. It is accompanied by a valuable diagram of curves. He begins by calling attention to the value of the system on which his calculations are based, namely, the mere registration of the days of which rain falls in each locality. Considering that in our latitudes changes of vapour tension and of relative humidity do not concur, it is simpler than measuring the quantity of rain or snow. The probability of a downfall depends upon two conditions, the degree of relative humidity between, say 100 and 3,000 metres altitude, and the favourable or unfavourable circumstances for the formation of an ascending current, or, firstly, on the rate of decrease of temperature with height; secondly, on the slope of the ground towards the direction of the wind, while the quantity depends also on the quantity of vapour contained in a volume of air, and so, *cæteris paribus*, on the temperature. He then gives a detailed account of the authorities from whom he has derived his materials. The selected stations are well distributed over the greater part of the northern hemisphere, including the North Atlantic, and have most of them afforded records during more than ten years. As in his former writings on the subject, he represents graphically the means of groups of neighbouring stations having similar annual distribution of rainfall, but annexes a table showing the actual numbers for each station. The diagram exhibits the probability of rain in each month for each district.

Feb. 15.—In this number Dr. Koppen concludes his remarks on the yearly periods of probability of rain. The paper, which is illustrated by elaborate tables, contains much valuable information respecting the times of year at which rain is most and least probable in a great number of countries and districts of the northern hemisphere.

Gazzetta Chimica Italiana, Anno VI., 1876, Fascicolo I.—Synthesis of the sulpho-tannic acids, by Hugo Schiff. The author in this paper treats of phenol-sulphuric anhydride, trichlorhydroquinone-sulphuric acid, sulphopyrogallic acid, sulphotannic and pentacetosulphotannic acids, the sulpho-acids of phoroglucin, &c.—On the elasticity of metals at different temperatures, by G. Pisati. In this paper the author investigates the elasticity of iron and steel, arriving at the following formula:—

$$K = \frac{P.L_0(1 + \alpha t)}{\pi r_0^2 (1 + \alpha t)^2 . l} = \frac{P.L_0}{\pi r_0^2 . l} \cdot \frac{1}{1 + \alpha t}$$

where K is the modulus of elasticity of stretching force, P the weight which acting on the length of wire L, produces the lengthening l, α is the co-efficient of linear expansion.—Modification of the process for the extraction of alkaloids in poisoning of the viscera, by F. Selmi.—On a method of detecting traces of phosphoric acid in toxicological researches, by F. Selmi.—On the use of phyllocyanine as a reagent, by Guido Pellagri.—Action of iodide of allyl and zinc on oxalic ether, by E. Paterno and P. Spica.—Chemical researches upon twelve coloured solids found at Pompeii.—The remainder of the part is occupied by extracts from foreign journals.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, May 1.—"On the Origin of Windings of Rivers in Alluvial Plains, with Remarks on the Flow of Water round Bends in Pipes," by Prof. James Thomson, LL.D., F.R.S.E. Communicated by Prof. Sir William Thomson, F.R.S.

In respect to the origin of the windings of rivers flowing through alluvial plains, people have usually taken the rough notion that when there is a bend in any way commenced, the water just rushes out against the outer bank of the river at the bend, and so washes that bank away, and allows deposition to

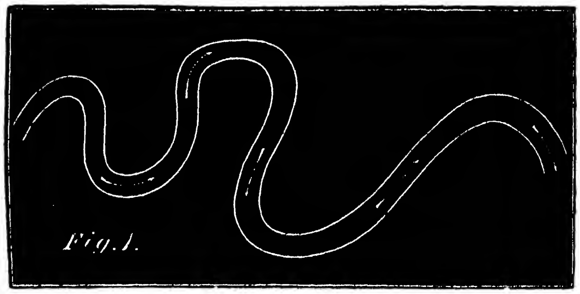

Fig. 1.

occur on the inner bank, and thus makes the sinuosity increase. But in this they overlook the hydraulic principle, not generally known, that a stream flowing along a straight channel and thence into a curve, must flow with a diminished velocity along the outer bank, and an increased velocity along the inner bank, if we regard the flow as that of a perfect fluid. In view of this principle, the question arose to me some years ago, *Why does not the inner bank wear away more than the outer one?* We know by general experience and observation that in fact the outer one does wear away, and that deposits are often made along the inner one. *How does this arise?*

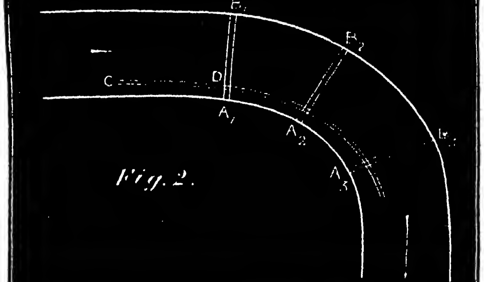

Fig. 2.

The explanation occurred to me in the year 1872, mainly as follows:—For any lines of particles taken across the stream at different places, as A_1B_1, A_2B_2, &c., in Fig. 2, and which may be designated in general as AB, if the line be level, the water pressure must be increasing from A to B, on account of the centrifugal force of the particles composing that line or bar of water; or, what comes to the same thing, the water-surface of the river will have a transverse inclination rising from A to B. The water in any stream line C D E [1] at or near the surface, or in any case not close to the bottom, and flowing nearly along the inner bank, will not accelerate itself in entering on the bend, except in con

[1] This, although here conveniently spoken of as a stream-line, is not to be supposed as having really a steady flow. It may be conceived of as an average stream-line in a place where the flow is disturbed with eddies or by the surrounding water commingling with it.

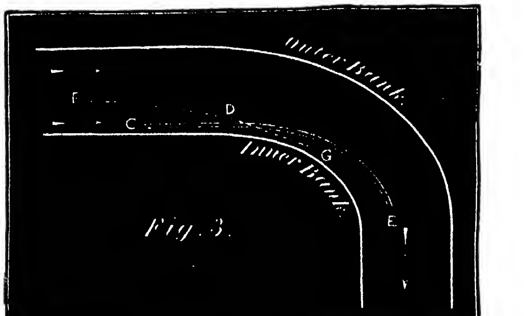
sequence of its having a *fall of free-level* in passing along that stream-line.[1]

But the layer of water along the bottom, being by friction much retarded, has much less centrifugal force in any bar of its particles extending across the river; and consequently it will flow sidewise along the bottom towards the inner bank, and will, part of it at least, rise up between the stream-line and the inner bank, and will protect the bank from the rapid scour of that stream-line and of other adjacent parts of the rapidly flowing current; and as the sand and mud in motion at bottom are carried in that bottom layer, they will be in some degree brought in to that inner bank, and may have a tendency to be deposited there.

On the other hand, along the outer bank there will be a general tendency to descent of surface water which will have a high velocity, not having been much impeded by friction; and this will wear away the bank and carry the worn substance in a great degree down to the bottom, where, as explained before, there will be a general prevailing tendency towards the inner bank.

Now further, it seems that even from the very beginning of the curve forward there will thus be a considerable protection to the inner bank. Because a surface stream-line C D, or one not close to the bottom, flowing along the bank which in the bend becomes the inner bank, will tend to depart from the inner bank at D, the commencement of the bend, and to go forward along D E, or by some such course, leaving the space G between it and the bank to be supplied by slower moving water which has been moving along the bottom of the river perhaps by some such oblique path as the dotted line F G.

It is further to be observed that ordinarily or very frequently there will be detritus travelling down stream along the bottom



and seeking for resting places, because the cases here specially under consideration are only such as occur in alluvial plains; and in regions of that kind there is ordinarily[2] on the average more deposition than erosion. This consideration explains that we need not have to seek for the material for deposition on the inner bank in the material worn away from the outer bank of the same bend of the river. The material worn from the outer bank may have to travel a long distance down stream before finding an inner bank of a bend on which to deposit itself. And now it seems very clear that in the gravel, sand, and mud carried down stream along the bottom of the river to the place where the bend commences, there is an ample supply of detritus for deposition on the inner bank of the river even at the earliest points in the curve which will offer any resting place. It is especially worthy of notice that the oblique flow along the bottom towards the inner bank begins even up stream from the bend, as already explained, and as shown by the dotted line F G in Fig. 3. The transverse movement comprised in this oblique flow is instigated by the abatement of pressure, or lowering of free-level, in the water along the inner bank produced by centrifugal force in the way already explained.

It may now be remarked that the considerations which have in the present paper been adduced in respect to the mode of flow of water round a bend of a river, by bringing under notice, conjointly, the lowering of free-level of the water at and near the inner bank, and the raising of free-level of the water at and near the outer bank relatively to the free-level of the water at middle of the stream, and the effect of retardation of velocity in the layer flowing along the bed of the channel in diminishing the centrifugal force in the layer retarded, and so causing that retarded water, and also frictionally retarded water, even in a straight channel of approach to the bend, to flow obliquely towards the inner bank, tends very materially to elucidate the subject of the mode of flow of water round bends in pipes, and the manner in which bends cause augmentation of frictional resistance in pipes, a subject in regard to which I believe no good exposition has hitherto been published in any printed books or papers; but about which various views, mostly crude and misleading, have been published from time to time, and are now often repeated, but which, almost entirely, ought to be at once rejected.

[1] It must be here explained that, by the *free level* for any particle, is to be understood the level of an atmospheric end of a column, or of any bar, straight or curved, of particles of statical water, having one end situated at the level of the particle, and having at that end the same pressure as the particle has, and having the other end, consisting of a level surface of water, freely exposed to the atmosphere, or else having otherwise atmospheric pressure there; or briefly we may say that the *free-level* for any particle of water is the level of the atmospheric end of its *pressure column*, or of an equivalent ideal pressure-column

[2] That is to say, except when by geological changes the causes which have been producing the alluvial plane have become extinct, and erosion by the river has come to predominate over deposition

Mathematical Society, May 11.—Prof. H. J. S. Smith, F.R.S., president, in the chair.—Dr. Logan was elected a member of the Society.—Mr. Tucker communicated a paper by Mr. S. A. Renshaw, on the inscription of a polygon in a conic section, subject to the condition that each of its sides shall pass through a given point by the aid of the generating circle of the conic. The inscription of a polygon in a circle, subject to the like condition, has been accomplished by several eminent geometers, in a remarkably easy manner by the late Mr. Swale. The object of Mr. Renshaw's paper is to show how, by an easy transformation, effected by means of the generating circle, the construction of the problem in the circle can be rendered available to the resolution of the same problem in the conic sections. The author draws figures exhibiting the inscription of a pentagon in an ellipse, and of a quadrilateral in a hyperbola. Mr. Renshaw also extends some other properties (for the circle) given by Mr. Swale in the *Liverpool Apollonius* (p. 45) to the conic sections.—Prof. Cayley then spoke on the representation of imaginary quantities by an (n, n) correspondence. The Chairman and Dr. Hirst spoke on the subject of this paper. Prof. Cayley having taken the chair, the President communicated two notes. The first was on a theorem relating to the Pellian equation. Let D be any integral number, let T and U be the least integral numbers which satisfy the Pellian equation $T^2 - DU^2 = 1$; and let $\Omega_1, \Omega_2, \Omega_3, \ldots \Omega_{2n}$ be the period of complete quotients of the form $\frac{\sqrt{D} + Q}{P}$ which is obtained in the development of the root of any quadratic equation of determinant D in a continued fraction. The equality

$$\Omega_1 \times \Omega_2 \times \ldots \times \Omega_{2n} = T + U\sqrt{D}$$

was established in the note, and an expression for the number of non-equivalent quadratic forms of determinant D was deduced from it. The second note was on the value of a certain arithmetical determinant. Let (m, n) represent the greatest common divisor of m and n; and let $\psi(m)$ represent the number of numbers prime to m, and not surpassing m: the equality

$$\Sigma \pm (1, 1)(2, 2) \ldots (m, m) = \psi(1)\psi(2) \ldots$$

was established in the note, and several consequences deduced from it.

Zoological Society, May 16.—Dr. A. Gunther, F.R.S., vice-president, in the chair.—Dr. P. Comrie exhibited and made remarks on the zoological specimens collected by him during the survey of the south-eastern coast of New Guinea by H.M.S. *Basilisk*.—Dr. Gunther exhibited and made remarks on a collection of Mammals from the coast of Borneo, opposite to Labuan. Among these were especially noticed a young example of a Monkey (*Macacus melanotis*) of which the exact habitat was previously unknown, and a new species of *Tupaia*, proposed to be called *T. minor*.—Dr. Gunther also read an extract from a letter recently received from Commander Cookson, R.N., stating that he was bringing home from the Galapagos Islands a living pair of the large Land-tortoise, of Albemarle Island. Commander Cookson stated that the male of this pair weighed 270 lbs., the female 117 lbs.—Mr. Sclater exhibited the skin of a rare Pacific Parrot (*Coriphilus kuhli*), which had been obtained by Dr. T. Hale Streets, U.S. Navy, at Washington Island, of the Palmyra group, and had been sent to him for examination

THURSDAY, JUNE 8, 1876

ON THE ORGANISATION OF THE PROFESSION OF CHEMISTRY

IT has probably happened to many young men who have fallen within the attraction of chemistry at the Universities or elsewhere to receive from their elders the prudent warning—chemistry is not a profession. Nor has this warning, or the fact conveyed in it, been without influence upon the number of chemical students. The complaint is often heard that original research in chemistry is at a low ebb in England at the present time. Comparatively few have both inclination and income enough to pursue chemistry as a scientific study without making it also in some way a means of livelihood. Contributions to biology come chiefly from members of the medical profession, contributions to mechanical science from engineers, contributions to chemistry from those who make a living by teaching or practising chemistry, and in proportion as a knowledge of this science opens a career, and is recognised as the basis of a profession will a twofold gain accrue. The character and attainment and number of those engaged in educational or practical chemistry will be raised, and as a consequence the quality and number of the contributions made to scientific chemistry will increase also.

At the present time there is a considerable and an increasing demand for young men having a knowledge of chemistry, as teachers, as laboratory assistants, as analysts or experimentalists on chemical and other work. But, partly because the importance of chemistry has not long been recognised, partly perhaps for want of organisation, to be a chemist does not constitute a definite vocation which a young man of the professional classes may choose with the same confidence as to be a doctor or a lawyer.

A vigorous attempt is now being made to organise an Association, or Guild, or Institute of Chemists, membership of which should confer a professional status and imply fitness for duties requiring chemical knowledge and experience.

Under the Act of Parliament for the prevention of adulteration of food and drink, and of drugs, passed in 1872, a number of persons have been appointed in all parts of the country as analysts. It must frequently have been a difficult task to find "persons possessing competent medical, chemical, and microscopical knowledge" to fill these posts. Where those with whom the appointment lay took pains to assure themselves of the fitness of their nominee, probably as good appointments were made as if professional chemists already formed a well defined class. But a definition and separation of qualified chemists, such as membership of the proposed Institute might effect, would serve as a guide to those charged with the duty of making such appointments, and would be a barrier against the nomination of wholly unfit persons.

On the other hand, it is worth remarking that the existence of a technical qualification is sometimes unfavourable to the selection of the best out of several candidates who possess it. The friends of an inferior candidate are apt to believe that all who possess the qualification are capable of doing the required work properly, and that the particular choice may fairly be determined by other considerations.

Employment of an unofficial kind, it may be thought, is not likely to be given to incompetent persons, since the employer has an immediate personal interest in being well served. But here also the existence of a distinct qualification, such as a licence to practise as chemist, granted after examination by an authorised body, would aid the choice of the employer, and would increase the chance of employment to those properly qualified.

The duties which fall to the lot of men engaged in general chemical practice are perhaps less important than those which are discharged by medical practitioners, and the persons who consult or employ chemists are, as a rule, more capable of selecting a qualified practitioner than the general public. The need of a professional stamp is therefore much less than in medicine. With this limitation, the same reasons which have led to the establishment of a legal distinction between the doctor holding a diploma and the quack doctor, would seem to favour the establishment of a similar distinction between the professional chemist and the amateur.

At a meeting held recently in the apartments of the Chemical Society at Burlington House, which was attended by a large number of the leading members of the Chemical Society, it was unanimously resolved that it is desirable that an organisation of professional chemists should be effected, and that for this purpose a body should be formed, having authority to issue certificates of competence. The questions which next arose, as to the nature of the organisation, and as to the steps by which it might obtain legal recognition, led to the consideration of the advantages or disadvantages of connecting the proposed organisation with the Chemical Society.

This Society includes among its Fellows the most prominent and by far the greatest number of those who are following chemistry as a profession. It has also the advantage of long standing, having been founded in 1841, of an established position, and last but not least, of incorporation by Royal Charter. Probably the existence of the Chemical Society might hinder the granting of a Charter of Incorporation to the proposed Institute. It is therefore clear that if the Chemical Society could undertake to issue licences to practise in chemistry, or certificates of competency, it occupies in some respects an advantageous position for doing so.

Nor does it appear that such an undertaking would exceed the wide discretion which is granted to the Society by its charter. The objects of the Society were defined by its founders to be "the promotion of chemistry and of those branches of science immediately connected with it, by the reading, discussion, and subsequent publication, of original communications." Here we breathe the upper air of pure science, of knowledge for its own sake. But the objects which the Charter recites are—"The general advancement of chemical science, as intimately connected with the prosperity of the manufactures of the United Kingdom, many of which mainly depend on the application of chemical principles and discoveries for their beneficial development, and for a more extended and economical application of the industrial resources and sanatory

condition of the community." The Charter proceeds to constitute the Fellows of the Society one body politic and corporate, and empowers a General Meeting of the Fellows, *inter alia*, to "enter into any resolution and make any regulation respecting any of the affairs and concerns of the said body politic and corporate that shall be thought necessary and proper."

It has been urged that it would be difficult to make a distinction between ordinary Fellows of the Chemical Society and qualified practitioners admitted and registered through the agency of that Society. This difficulty lies chiefly in the choice of an appropriate name. "Licensed Fellow" has an awkward sound, and "Licentiate" is, by analogy, a lower title than "Fellow." There seems to be nothing in the Charter to forbid such a distinction, which would be for external use only, and would not differentiate the holders of licenses in respect of eligibility to Council or any other privilege, from ordinary Fellows of the Society. Indeed it does not appear that it would be *ultra vires* for the Chemical Society to grant certificates of competency as Chemists to those who are not Fellows of the Society.

Leaving, however, the question of what is legally practicable, we must confess that in spite of our sympathy with the proposed organisation, we doubt the expediency of effecting it through the instrumentality of a society which has hitherto occupied itself solely with the extension and diffusion of knowledge.

The first granting of licences would be presumably to those who have already an established position as practical chemists. The task of selection would be invidious, and would involve a responsibility from which the Chemical Society would naturally shrink. Subsequently, we presume, licences would be granted upon an examination, and it would seem to be a wide departure from the functions which the Chemical Society has hitherto performed, for it to constitute itself an examining body, or to undertake the appointment of a Board of Examiners.

If no other plan were practicable we might hesitate to express our dislike to the proposal that the Chemical Society should enter upon this new career. Existing examining bodies and bodies that issue certificates to those who pass their examinations, are ready to hand. It should not be difficult to obtain the co-operation of the Universities in this matter, and a Board of Examiners appointed by the Universities of Oxford, Cambridge, and London, without necessarily any restriction that those applicants should have received a University degree, would probably command and deserve confidence better than a Board nominated by a newly formed Institute or even by the Chemical Society.

At least such a scheme might serve at the outset; and when through its operation chemistry had begun to be consolidated and recognised as a profession, the proposed Institute of Professional Chemists might be formed, and undertake for the future the selection of its own members.

THE ENDOWMENT OF RESEARCH

Essays on the Endowment of Research. By Various Writers. (London: King and Co. 1876.)

IT is to the untiring exertions of Dr. Appleton in the cause which is here pleaded, that we are indebted for this valuable combination of essays. The eminence and competency of the writers give it an overwhelming force of authority and reason. The list of contributors is as follows:—The Rector of Lincoln College, Oxford, Mr. James Cotton, late Fellow of Queen's College, Dr. Appleton, Fellow of St. John's College, Mr. Sayce, Fellow of Queen's College, Mr. Henry Sorby, F.R.S., President of the Microscopical Society, Mr. Cheyne, Fellow of Balliol, one of the company for the revision of the Bible, Mr. Thiselton Dyer, late of Christ Church, Assistant Director of the Royal Gardens, Kew, Mr. Nettleship, Fellow of Corpus Christi College. These eight writers treat of various aspects of the Endowment of Research, such as the need for it, the applicability of college revenues to the purpose, the incompatibility of teaching and research in ten essays. No doubt more remains to be written on the subject, more will have to be said, and what is said will need to be said a great many times before the public—even its more intelligent section—comprehend the importance of research or the necessity for its endowment. The present volume may be taken as a fair statement of some of the most important arguments in the matter, and should furnish the starting point for a determined and unwearying effort *permanently* to affect public opinion in the right direction. Widely as we should wish to see this book read amongst the laymen of science, the Philistines and those who prophesy to them, politicians and professional reformers, it will certainly be found quite as valuable as by any of these, by men of science. Men of science will find in the present volume data and suggestions which should aid them greatly at this critical moment to determine what they will urge upon the government, as the true relationship between the State and scientific research.

The substance of these essays may be summarised in the form of a series of questions and answers, the latter being frequently reiterated, as it were, by one after another of the essayists.

1. What is this "research" which you propose to endow? It is more fully described as "scientific research." It is the "disinterested pursuit of knowledge" (Pattison), the following up of "science for science sake" (Pattison), and "by the introduction of the utilitarian motive its strictly scientific character is destroyed" (Appleton). It is co-extensive with the whole range of human knowledge, and comprises such groups as "historical science," "mental science," "linguistic" science, (Sayce, Cheyne, Appleton), equally with molar and molecular physics, astronomy, geology and biology. It has its end and aim in itself, viz., the attainment of truth. We assume that it is necessary for man, necessary for his progress, for his happiness if you please, but inevitable whether for weal or for woe, predestined by the noblest and most commanding passion of his nature—*the love of the truth*. To the ignorant or unthinking some truths appear to justify this craving on account of the material gratification which their knowledge enables mankind to obtain, whilst the acquirement of other truths appears to these persons superfluous. A consideration of any one department of knowledge is, however, sufficient to show us "that nature is one, and that no man dare put his finger on any of its secrets and say this is a mere field for ingenious curiosity" (Dyer). The narrower type of utilitarian, with his petty measure of what is and what is not for the happiness of mankind,

has no scope for discussion in this matter; he must bow before the inexorable domination of an impulse planted in the very elements of our being. The importance to the community of mature study and scientific research has been recognised in the past both in our own and other countries; at the present day it is very much less appreciated in England than elsewhere. The immense fields which lie open to us, with their harvest of knowledge waiting for reapers, are to some extent indicated in the essays by Mr. Dyer, "On the Needs of Biology," Mr. Cheyne, "On the Study of the Bible," of Mr. Sayce, "On the Needs of the Historical Sciences." Over and over again it will be necessary to explain, as these essays do, how great and of what kind are the stores of knowledge which students see within their grasp, and how difficult and all-absorbing is the task of reaching them. It is the duty of men of science incessantly to exert themselves in inducing the great public, even though this generation and its successor prove stiff-necked and hardened in heart, to believe their report of the promised land.

2. Granting that "scientific research" is a good thing and to be wished for as the highest development of the life of the community, why should it be endowed? Why should persons be supported by public funds to carry on research? Why not leave every man to follow research for his own delectation, and trust to the attractions which it possesses for its increased cultivation?

Because it cannot be successfully carried on, in the present conditions of society, by men who have to earn their bread in any of the usual avocations. Mr. Sorby, in his "Personal Experience" (Essay No. VI.), with convincing simplicity and candour, tells us how all absorbing is research, how much may be lost by withdrawing the man who is engaged in an investigation, even intermittently, from his pursuit, how necessary is ample time, freedom from anxiety, health of body, "readiness of the mind to take advantage of every circumstance that may occur to press forward the inquiry in the line of truth." Fortunately Mr. Sorby is endowed with a patrimony, and he says, "I never could have done what I have been able to do if it had been necessary for me to attend to any business or profession as a means of support." Men who are capable of or disposed to engage in scientific research are not always thus situated. Unless we are prepared to lose the services which these persons might render--some of them perhaps the very ablest and most productive minds--and to rest our hopes on the chance coincidence of fortune and ability, as for instance in the cases of Lyell, Darwin, and Grote, we must accept a scheme for providing such persons with pecuniary support out of public funds. To a certain extent we already do this, but very inadequately. The posts in the British Museum, the Greenwich Observatory, and a few others here and there, are of the nature of endowments for research. But these are so few in number and so meanly paid that they cannot be regarded as exercising any important influence in attracting men of ability into the career of research. Among Continental nations but especially in the German empire, in proportion to the wealth of the countries in question, very much larger provision is made for the encouragement of research--and with the most perfect success, as tested by results. In Germany, owing to the special view which is taken in that country of a "University," there are 1,250 posts designed for the promotion of research with stipends varying in value from 80*l.* to 600*l.* a year. There is one such post to every 33,000 of the entire population, or to every 1,600 males between the ages of twenty and thirty years. The total cost of the support of these persons and the laboratories, libraries, &c., with which they are connected (leaving out of consideration such special institutions as are the exact counterparts of our British Museum, observatory, &c.) cannot be less than 600,000*l.* annually. An equivalent provision in England would necessitate the creation of 1,000 posts at an annual expense of 800,000*l.*, making allowance for the fact that money has at least double the value in Germany which it possesses in England, in relation to the purpose under consideration. It is curious to observe that this sum (800,000*l.*) corresponds very closely with the estimated value of the incomes of the ancient University institutions of Oxford and Cambridge—where, however, the money is not applied to the endowment of research.

3. The reference to Universities and to Oxford and Cambridge brings to mind a suggestion which at first sight appears admirable. "Granted that research must be endowed, there is yet great difficulty in persuading practical men to pay for it in the pure and unalloyed form. It can only be a pleasure to the investigator to communicate to pupils the results which he obtains in his researches, clearly it is his natural function to teach. In fact you have already got what you want in the Fellowships of Oxford and Cambridge, many of the holders of which reside in those Universities and teach and doubtless spend a large portion of their time in research. Abolish the non resident Fellowships, remove the immoral condition of celibacy, give two or three Fellowships to the men who stay longest in the place, require them all to teach at a cheap rate (this will be well received by the public) and you may be sure that they will devote all needful energy to original research. Is not your demand for the endowment of research liberally met in this way?" Certainly not.

The deadly error embodied in the above bids fair at the present moment to destroy the good hope which we at one time possessed of seeing at Oxford at any rate (it is from Cambridge that the mischief has come) a portion of collegiate endowments applied to the support of research. The chief care of the Oxford men who write in Dr. Appleton's volume is to combat the insidious doctrine that *research* is compatible with *teaching*, in the narrow sense in which teaching is understood in Universities which like Oxford and Cambridge are carried on upon the plan originated by and worthy of the Jesuits (see Pattison, Essay No. 1), viz., that in which competition by examination for prizes forms the pivot of all activity. The watchwords of the German Universities "Lehrfreiheit" and "Lernfreiheit," are (save to a very few) unknown, the idea which they express equally so, in this country.

The suggestion that teaching and research should go hand in hand appears at first sight admirable, because there can be no doubt that in the wider and higher sense of the word "teaching," the investigator is and must be a teacher. In the German Universities it is a small tax upon the professor or holder of a research endowment to give a course of lectures upon the subject with the study

of which he is occupied. He is entirely free from the influence of the Jesuit's examination system; that has been long since abolished (where it existed) in German Universities. He is never concerned for one moment with the thought as to what place his hearers may take in an examination—such examination as there is being entirely in his own hands—and having very little importance attached to it. Moreover, he cannot (at any rate in the early part of his career) make anything considerable by the fees of his hearers, and has to look for his promotion and increase of income solely to *success in the occu-* [illegible] *which his chair assigns to him, namely, original research.*

The preparation of students for an examination by the results of which they are to gain or fail to gain valuable money-rewards, is a business by itself; and the man appointed to carry on this business, especially when his own income and his promotion depend upon his success in placing his pupils well in the examination, cannot pay much attention to other things. He is in a totally different position from that of the German professor. He is in the position which Mr. Sorby deprecates, viz., that of having an anxious commercial pursuit. But, worse still, as Mr. Pattison and Mr. Nettleship point out in their essays, he deals with knowledge and the results of study in such a way (viz., for examination purposes) that he necessarily is liable to become less fitted than any other man of business to pursue knowledge for its own sake. He and his pupils take up a radically false position with relation to knowledge.

The essays of Mr. Pattison and Mr. Cotton are particularly interesting as showing how the present enormous revenues of the Colleges and Universities of Oxford and Cambridge came to be employed, as they are for the most part, in the cheapening of cramming (as Mr. Sayce does not hesitate to call it) and the reward of success in being crammed, or in the subvention of resident college-lecturers and tutors on the one hand, and non-resident competition prize-men on the other. Originally this was not the case; Fellowships were even founded for the express purpose of relieving their holders from the distraction of teaching, in order that they might devote themselves to study. It was unfortunately at a time when the Church was entering upon a new phase of its history, no longer to be the great representative of learning and science, but something very different, that Leicester and Laud handed over the University to the Colleges and the Colleges to the Church. The Fellowships became so much capital, by means of which, in virtue of their monopoly of education, the Colleges were able to convert themselves into what they have with general approval, but to the detriment of science and letters, become—proprietary schools[1] for the "finishing" of young gentlemen. Under the present system the resident Fellow doubles his income through the division of the monopolised fees, whilst the young gentleman's parents pay half[2] what they would have to pay elsewhere for the same amount of constant supervision, cramming, and "direction."

Whatever portion of the collegiate revenues is retained by the new University Commissioners for the College tutors, or as the Oxford Hebdomadal Council has expressed it, for "education" (as that word is understood at the English Universities) is clearly enough lost to research. This proposition is perhaps the main result of the arguments adduced in the essays of the rector of Lincoln, Dr. Appleton, Mr. Sayce, and Mr. Nettleship.

4. All this being admitted, namely, that it is a matter of urgent importance to provide an extensive series of fairly-remunerated posts to be held by persons constantly engaged in research, unencumbered even by the plausible condition of preparing young men for examination, the practical questions come—which with Englishmen are generally the first questions—namely, Whence is the money to be obtained for this purpose, and how are you to ensure that true "research-men" will get the posts supposing that they are once created?

These are two distinct questions. As to the first the answer is simple. It is only through the direct intervention of the Government that the thing can be done. Government may assign for this purpose a large part of the revenues of Oxford and Cambridge, of City Companies, or of the Irish Church; or the sum required may be met annually by the taxes. The "Essays" have chiefly in view, no doubt, the appropriation of a part of the revenues of Oxford and Cambridge to this purpose. At the same time we must remember that even were some 200,000*l.* a-year detached from those institutions and deliberately and simply assigned to the promotion of research under State control, yet even then only a portion of the national requirements would be met. A larger sum than this is needed to carry out even a moderate scheme. When, however, it is proposed to leave the 200,000*l.* a year under the control of its present administrators with general directions to them to employ it in the encouragement of research, we must contend that there is very strong reason, indeed, for an additional altogether independent and strictly national endowment of research—such as has been hinted at by Lord Derby—and such as is carried out by continental Governments.

The second question as to the means to be adopted in order to avoid jobbery and sinecurism in connection with the proposed series of posts, is not discussed in any way in the volume under review. It is, however, one of the most serious questions, and we shall therefore venture very briefly to furnish an answer which is, as far as we can see, completely satisfactory. In a question like this, of serious practical importance, the most conclusive answer is to be found in an existing solution of similar difficulties in a very closely similar case.

This we possess in the great German University system. Whatever objections Englishmen may have to German Universities as teaching bodies, the fact remains that as an arrangement for the endowment of research on a truly national scale they are the most unqualified success. Research *is* endowed by this system and *is* abundantly carried on, and this without (to the writer's knowledge) a suggestion or imputation of jobbery or sinecurism in connection with it.

The elements of this success in the German system are the following:—1. The appointments are held by twenty-one groups of men engaged in research. 2. By custom and the conditions of society (legislative prohibition would

[1] See Prof. Max Müller in the *Academy*, May 11.

[2] The Oxford undergraduate pays on an average 20*l.* a year for being prepared for examination. A well-known "grinder" for the Indian Civil Service examinations charges, I believe, 100*l.* a year for similar preparation.

have to be called into use in England) these corporations are not allowed to make money by engaging in commercial pursuits or the keeping of boarding-schools. (3) The appointments are graduated in value from 80*l.* to 400*l.* per annum. (4) New members are chosen in any one corporation by co-optation. The promotion of existing members is effected by the same process—one corporation often inviting a member of another to leave his old associates in order to enjoy an increased salary, or increased facilities for research. This co-optation is carefully supervised but not directed by the State Government. (5) Since commercial operations, such as the acquirement of a large revenue by any corporation from the fees of pupils or wards committed to its care, are out of the possibilities of the case—the sole motive which affects the various corporations in their choice of colleagues is a desire to secure colleagues of eminence in the avocation which is assigned to the corporations, namely, research, and in this way to maintain a high reputation for the corporation and congenial association for its members. (6) The result of this is, that the whole stimulus which the prospect of a step-by-step accession of income from 80*l.* to 400*l.* or 600*l.* per annum can bring to bear upon the nature of man is constantly at work in urging those who enter upon this career to give their full energies to research, and research alone. The habit of research so stimulated and fostered, remains even after a career of twenty or twenty-five years—the length of service which entitles the German professor to retire upon full pension.

The enormous fertility of Germany in all kinds of research is the outcome of this simple and healthy system. There does not appear to be any reason why a parallel system applied in this country should not produce parallel results. E. RAY LANKESTER

QUAIN'S ANATOMY

Quain's Elements of Anatomy. Eighth edition, edited by Dr. Sharpey, Dr. Allan Thomson, and Mr. E. A. Schäfer. Two Vols. (Longmans, Green and Co., 1876.)

THE seventh edition of Quain's "Anatomy" appeared nine years ago under the conjoint editorship of Dr. Sharpey, Dr. Thomson, and Dr. Cleland; in the eighth Mr. E. A. Schäfer's name is found on the title page instead of that of the last-named anatomist. The new edition contains much new matter, and with a larger as well as a clearer type, covers nearly an extra hundred and sixty pages.

The arrangement of the subject-matter is considerably modified in the direction of improvement; the descriptive account of the bones, joints, muscles, vessels, and nerves, together with the surgical anatomy, occupying the first volume; the second, containing the general anatomy or histology, the structure of the different viscera, the organs of special sense, and the embryology.

A much-needed advance has been made in the sections devoted to osteology and myology, which consists in the introduction of paragraphs on general morphology. Teachers of anatomy are too apt to entirely neglect those great strides that have been made in zoology, many of which have an important bearing upon the way in which the human skeleton and soft parts should most certainly be regarded. We, upon this view of the question, are therefore glad to find among other innovations, a classified list of the bones of the head, and their typical component parts, the nomenclature adopted being that employed by comparative anatomists.

The introduction of nitrate of silver, osmic and chromic acids, logwood, &c., as adjuncts to histological manipulation, as well as the efforts of many able investigators, have rendered corresponding changes necessary in the sections of the work devoted to the microscopic structure of the tissues and organs; and Mr. Schafer has here introduced several fresh illustrations, and much new matter, which makes the "general anatomy" by itself an invaluable summary of the most modern aspect of histology. The development of blood corpuscles, the ground-substance of connective tissue, the ultimate nature of muscle, the serous membranes and their lymphatics, have received the greatest additions in this portion of the work.

Dr. Allen Thomson has entirely re-written the chapter on embryology, having embodied all the more recent results in this rapidly advancing department of biological science, arrived at by Foster and Balfour, Parker, Mihalkovics, Waldeyer, and others. The whole forms a most excellent account of human embryology, as far as it can be known from the incomplete direct, and the much indirect evidence which can be brought to bear upon it.

The editors acknowledge the assistance of Dr. Gowers, Assistant-Physician to University College, in the revision of the paragraphs on the Cranial Nerves; and in the chapter on the Brain and Spinal Cord, Dr. Gowers has introduced a valuable account of the cerebral convolutions, together with some excellent drawings, more elaborate than those of Ecker. The nature of the many layers of the cerebral cortex is fully discussed, at the same time that a careful abstract of the terminology of Meynert is given, with additional figures.

There is one minor zoological error which we have not seen corrected in any anatomical or physiological textbooks. It is in the nomenclature of the animals with peculiarly small blood-discs. The "Napu Musk Deer" is said to possess the smallest blood corpuscles of all mammalia. It is now known that the Musk Deer has no special kindredship with the Chevrotains, or Tragulidæ, to which group the Javan Chevrotain (*Tragulus javanicus*), which formerly went by the name of the "Napu Musk Deer," belongs. A reference to Mr. Gulliver's more recent paper[1] also shows that in the Indian Chevrotain (*Tragulus meminna*) the discs are equally minute.

With reference to the typography we think it much improved in all respects, but of the figures we cannot help remarking that sufficient care has not been taken by the printers in doing justice to the artists or the engravers. Several of the older woodcuts are, no doubt, much worn, but they, as well as the more recent ones, are printed much too black, considerably darker than in the previous edition.

OUR BOOK SHELF

Exercises in Electrical and Magnetic Measurement. By R. E. Day, M.A. (London: Longmans, Green, and Co., 1876.)

MR. DAY'S little book on Electrical and Magnetic Measurement seems to us likely to be of considerable

[1] Proc. Zoolog. Soc., 1875, p. 49.

service both to teachers and to students. The best proof of knowledge of any branch of physics, and the most practical result of the study of any such branch is the acquisition of the power of applying numerical calculation to every question where a numerical result can be obtained. The student knows that he understands a subject thoroughly when he can write down numbers to express definitely the amount of every effect observed and measured by experiment. The importance of numerical calculations in absolute measure is becoming daily more and more appreciated: and in the best English text-books numbers expressing quantities in absolute measure are now to be found, instead of the relative numbers that were alone obtainable from the text-books of only a few years ago. Mr. Day's book brings very fairly together such questions as are likely to present themselves to the student of electricity and magnetism. Anyone who has acquired sufficient knowledge to work through a considerable part of the exercises cannot fail to find them extremely useful.

We have observed some slips that ought to be corrected in future editions. Among them may be mentioned some of his exercises on the tangent galvanometer. No practical experimenter would think of using the tangent galvanometer in such a way as to bring the deflection to 89° 30′, as Mr. Day does in Ex. 23, p. 47, or to the high numbers that he refers to elsewhere. We find readings of Thomson's reflecting galvanometer given in degrees, minutes, and seconds. This seems rather absurd, to say the least of it. In a few of the exercises, as in Ex. 9, p. 33, the data are insufficient.

A few more definitions would, we think, be found useful. Some of the terms employed are uncommon, and some appear to be used somewhat ambiguously. Thus in Ex. 2, p. 17, the word *density* is wrongly used for quantity. Again *density* of an electric current is a term so unusual that some explanations regarding it seem all but necessary. The definition, given in Ex. 2, p. 72, as Bunsen's definition, appears a very incomplete one. According to it, a *current of unit density is a current of unit strength passing through a voltameter between two electrodes each one square millimetre in diameter*, and from this it would follow, we presume, that the so called density of the current is the same at every part of the voltameter and independent of the form of the voltameter. If so we cannot think of any possible use of such a name. The terms Farad and Weber, given by some of the practical electricians seem to be used indifferently in more senses than one. It is simply unpardonable, in the present state of the science, to *introduce* ambiguities of language.

On the whole, however, we are much pleased with Mr. Day's little book, and can warmly recommend it both to teachers and to those who are studying electricity and magnetism without the aid of a teacher.

Geological Survey of Victoria. Prodromus of the Palæontology of Victoria. Decade 3. By Frederick McCoy. (Melbourne. London: Trubner and Co., 1876.)

WE are glad to find that in spite of the unpromising news which has recently reached England concerning the present condition of the Geological Survey of Victoria, the palæontological work, which is in the hands of such a well-tried and indefatigable naturalist as Prof. McCoy, continues to make satisfactory progress. The present decade of the *Prodromus* is of more than local interest, containing as it does interesting new details concerning Owen's marsupial lion, the *Thylacoleo carnifex*. The result of Prof. McCoy's examination of more perfect specimens than those on which the first description species was based, is to suggest modifications in some of the views published by Prof. Owen, but to add confirmation to that author's main position concerning the carnivorous habits of the animal, a conclusion which was called in question by Dr. Falconer and Prof. Flower. Scarcely less interesting at the present time is the illustration and description of a species belonging to the sub-genus of *Nautilus*, known as *Aturia*. A similar form has been found by Dr. Hector in New Zealand, but in rocks of far older date, and the facts which have already come to light concerning the distribution in space and time of this remarkable genus are such as to invest it with the very highest interest both to the geologist and biologist.

On similar grounds the new species of Tertiary *Trigonia* and *Pleurotomaria* genera which were so abundant during earlier periods of the earth's history, but which, except in Australia, appear to have become almost wholly extinct at the close of the Mesozoic epoch—are especially worthy of the attention of the palæontologist. The other new forms illustrated in this decade, including a number of Trilobites and Tertiary Mollusca, do not call for any special remark. Prof. McCoy's scientific descriptions are admirably clear and exact, and his general remarks on the relationships and distribution of the species very valuable and suggestive. The engraving and printing of these decades afford evidence alike of the progress made by our Australian colonies and the liberality with which scientific research is supported in them. The plan of publication by decades, illustrating the palæontology of the countries geologically surveyed, was commenced in the United Kingdom by Sir Henry de la Beche, and has been followed both in Canada and India. The decades of the Victoria Survey are quite worthy to take rank, both as regards matter and form, with those of either of the older surveys we have mentioned; and higher praise than this it would scarcely be possible to add.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Scientific Poisoning

FOR giving instruction to *one person* in the art of poisoning without detection, the medical student, Vance, is undergoing the very lenient punishment of eighteen months' imprisonment. What would be the appropriate penalty to inflict upon the responsible editors of newspapers who initiate *the public generally* into Vance's secret?

CHEMIST

Pyrology—Quantitative Analysis by the Blowpipe

THE *estimation* of constituents in compounds by the blowpipe has been hitherto, as is well known, limited to the process of metallic (or, in the case of cobalt, arsenidal) reduction of oxides, &c., and that with regard to a very few metals only. I now propose to inaugurate a new plan, by which this rapid, elegant, and accurate method of analysis may (apparently) be applied far more generally, and, as I hope, successfully. In my published work "Pyrology, or Fire Chemistry," I have, with the exception of a few indications (as in the case of the insoluble balls formed by *lime* in *boric acid*), confined myself to qualitative research only, but many methods will suggest themselves to the attentive student of that book, by which qualitative may be readily extended to quantitative examination.

I propose to proceed more in the direction of a kind of *volumetric analysis* than of analysis by means of the successive *separation* of constituents, as in the "wet way," and I trust that the consideration usually accorded to novelty and the difficulties always inseparable from useful novelties will not now be refused by scientific Englishmen to my feeble initiatory researches, especially as I am (I believe) the first Englishman who has published much *original* matter on this subject. It seems likely that the operator who can, by reason of the *rapidity* of his methods, obtain the *mean of a number* of approximate analyses of a particular substance in the same or less time than that required by the employer of an abstractedly more correct but practically more

dangerous mode (from the failure of any one of the delicate manipulations introduced) for *one analysis*, will probably arrive in the end, at a result more closely approaching to the truth.

Blowpipe Assay of Ores, Furnace Products, &c., for COBALT.

1. The *rationale* of this process depends upon the observations (*a*), that a trace (say ·5 mgr.) of cobalt oxide affords, when dissolved in a bead of microcosmic salt, *the same* colour (violetish blue) which is afforded by the addition to a similar bead of *five times* as much oxide, or 2·5 mgrs.; and (*b*) that these relative quantities of cobalt oxide afford, when dissolved in *phosphoric acid* beads of the same weight (say 60 mgrs.), *perfectly different* colours; viz., *pink* as regards the smaller proportion, *violet* as regards the greater.

2. The corollary derivable from these premises seemed to me, therefore, that, the quantity of phosphoric acid being kept constant, it would require the addition of more *soda* to turn the pink bead than the violet bead *blue*; first, because violet already contains blue, and second, because the cobalt might be presumed to have already saturated, as a chemical base, part of the phosphoric acid.

3. I was *exactly wrong* in this assumption. Different quantities of soda were, indeed, required to azurise the two beads, but the *violet* bead required *more* than the pink one.

4. Without troubling the reader with tedious details, I may state here that each of three assays constantly showed the necessity of an addition of 14 mgrs. of fused sodium carbonate in order to azurise a 60-mgrs. bead of phosphoric acid, made pink by the solution in it of ·5 mgr. of pure cobalt oxide; and (by three other assays) an addition of 20 mgrs. of soda to azurise a 60 mgrs. bead made violet by 3·5 mgrs. of cobalt oxide. The ratio, therefore, stood thus:—

$$\begin{matrix} \dddot{\text{NaC}} & & \dddot{\text{NaC}} & & \text{CoO} & & \text{CoO} \\ 20 & : & 14 & :: & 3\cdot5 & : & \cdot5 \end{matrix}$$

or the violet standard of cobalt was to the pink standard, as 2·45 : 0·71. It would, by these assays, seem that every half milligramme between those extremes of cobalt oxide dissolved, requires the addition to the bead of one milligramme of fused sodium carbonate, in order to azurise a 60 mgrs. bead of pure phosphoric acid.

5. The way to operate is to compare, by reflected and transmitted light, the blue colour thus obtained, with that of two 60 mgrs. beads of *micro osmic salt*, having the above-named quantities of pure cobalt oxide respectively dissolved in them. Space does not allow me here to describe the *mechanical details* of operations, which must be conducted with the utmost care.

6. From these facts, the following analytical table, as regards *cobalt*, is deduced:—

CoO mgrs.		$NaCO_3$ mgrs.				
0·5	requires	14	=	0·83	per cent. of a 60 mgrs. phosphoric acid bead.	
1·0	,,	15	=	1·6	,, ,,	,,
1·5	,,	16	=	2·5	,, ,,	,,
2·0	,,	17	=	3·3	,, ,,	,,
2·5	,,	18	=	4·1	,, ,,	,,
3·0	,,	19	=	5·0	,, ,,	,,
3·5	,,	20	=	5·8	,, ,,	,,

The use of this table is shown in the following example:—

7. *Assay* (*for Cobalt only*) *of Smaltine, from a Freiberg Cabinet.*

			mgrs.	per cent.
α.	Weight of powdered ore crushed between agates	=	50	—
β.	Weight of powdered ore after roasting on aluminium plate...		18	36
	Therefore the loss in arsenic and volatile constituents	=	32	64
γ.	Weight of a new platinum wire with a ring of 1 diameter[1]	=	71·5	—
δ.	Weight of the same platinum wire with a bead of phosphoric acid fused on it	=	134·5	—
ε.	Weight of the bead and wire after 2·5 mgrs. of (β) had been dissolved in the former	=	124·0	—
ζ.	Weight of the bead and wire after the addition of fresh phosphoric acid[1]	=	132·5	—

[1] This refers to the "ringing forceps."

(This bead being *rose* colour,[2] *fused sodium carbonate* was cautiously taken up from an agate slab and dissolved in it under **O.P.**).

			mgrs.	per cent.
η.	Weight of soda required to colour to the *blue* of mic. salt with 2·5 CoO .		16·5	—

Now, by the above table (6), 16·5 mgrs. of *soda* correspond to 3 per cent. of a 60 mgrs. bead in *pure* CoO; and 2·5 mgrs. of pure CoO, requiring 18 mgrs. of soda, constitute 4·1 per cent. of the bead. Therefore we have the ratio—

$$4\cdot1 \ : \ 3 \ :: \ 100 = \tfrac{3}{4\cdot1}\text{ths of } 100 = 75 \text{ per cent.}$$

But, as this is the percentage of the *roasted powder*, or "regulus," we have—

Regulus in 100 mgrs.		Percentage of regulus. mgrs		Mgrs. of ore.	
36	:	75	::	100	= 20·08 per cent. cobalt.

Several assays were made with a similar result, but one other example is given here, with a different platinum wire.

				mgrs
α.	Weight of a platinum wire		=	61·0
β.	,,	ditto with bead of phosphoric acid	=	131·0
γ.	,,	roasted *smaltine* dissolved in (β).	=	2·5
δ.	,,	this wire with bead coloured rose pink with (γ)	=	118·5
ε.	,,	bead and wire with fresh phosphoric acid	=	121·0
ζ.	,,	sodium carbonate required to colour (ε) *blue*		16·5

8. These data would, of course, give a similar result. Roasting before O.P. on *aluminium plate* is so rapid and efficacious that the whole process only occupies about half an hour; with the *roasted powder*, about a quarter of an hour. A drop of water is placed on the powder to retain it under the blast.

In roasting, *nickel* oxide appears, yellowish green, on the surface, and might possibly be mechanically separated at this stage of the procedure.

W. A. R[illegible]

[1] This is necessary to make up the weight of the bead to 60 mgrs After the addition of soda, there is *no* loss from volatilisation.

[2] From the interference of iron and nickel oxides in the assay

Page's Introductory Text-book of Physical Geography

It has been pointed out to me that the same errors which I noted in this book (NATURE, vol. xiv. p. 26), had been corrected as regards Prof. Page's "Advanced Text-book" by Mr. Wallace three years ago. They can scarcely, therefore, be anything but wilful, and it is difficult to understand how they could be allowed to reappear. We do expect teachers of position at least to do their best to teach rightly; and when one has fallen into error it is certainly more manly to correct it than to stick to it, because it has once been committed. It is a good thing to teach science, but it is just the opposite deliberately to teach false science.

THE REVIEWER

OUR ASTRONOMICAL COLUMN

THE SECONDARY LIGHT OF VENUS.—By way of supplement to the historical notes on the luminosity of the "dark side" of the planet Venus in last week's "Astronomical Column," a brief enumeration of the various explanations of the phenomenon which have been offered from time to time may not be out of place here.

These resolve themselves into (1) reflected earth-light analogous to the lumière-cendrée exhibited by our moon, an explanation advanced by Schröter, Harding, and many others; (2) phosphorescence of the planet's atmosphere, suggested by Sir W. Herschel to account for the appearances remarked by Schröter, though looked for without success by himself, with which may be mentioned Pastorff's idea of a self-luminous atmosphere; (3) visibility by contrast—"might not a plausible explanation be given," asks Arago, "by referring it to a class of objects which are negatively visible, or which are rendered apparent by way of contrast?" (4) luminosity, similar to our polar-light (aurora borealis); (5) natural light-developments, as luminosity of the ocean; (6) a condition of

glowing fire, or intense heat of the surface, and (7) the *Künstliche Feuer* of Gruithuisen

There is one characteristic of the phenomenon abundantly verified by the numerous observers who have recorded it, which cannot be overlooked in our endeavours to arrive at its true cause, viz, its intermittent or only occasional visibility This alone appears to render more than one of the explanations which have been advanced highly improbable if not wholly inadmissible. There are also isolated observations which seem rather to favour one or other of the hypotheses Thus Schroter considered that the change in the colour of the faintly illuminated disc from reddish to ashy grey remarked by Harding, indicated a connection with our aurora borealis, in exhibitions of which similar rapid changes or alternations of colour are observed, and a very curious observation by Madler has been cited in the same direction On April 7, 1833, at 8 P.M., in a sky of extraordinary clearness and tranquillity, Venus, then in crescent phase, appeared to him accompanied by a beautiful radiating appearance, seven or eight straight rays, at times very bright and sharply defined at others fainter and more diffused, occupied the north west quadrant, and were gradually lost in the general ground of the sky The longest ray extended about 15 the shortest was about half that length, neither turning round the eye piece, nor viewing the planet in different parts of the field of the telescope, at all affected the phenomenon, which continued unchanged as long as Venus was observed that evening A figure of this appearance is annexed to Madler account of his observation

Zollner has expressed his conviction that under spectroscopic examination, the ash coloured secondary light of Venus will be found to present bright lines and it may be hoped that opportunities for such observation may occur during the present summer

By closely watching the form of the crescent towards the extremities further evidence of rotation in rather less time than is occupied by the earth in her diurnal revolution, may also be obtained But with this object, observations must be made at very short intervals In illustration of this may be quoted Madler's experiences on June 6 and 10 1836

	h m		
June 6,	10 41	Sid T	Both horns equally pointed, and the curvature quite elliptical
„	11 10	„	The same
„	11 6	„	The northern horn appears to be the more pointed
„	11 35	„	The northern horn certainly more pointed also at 11h 13
	11 56	„	Again uncertain
June 10,	11 14	„	Both horns alike
„	11 26	„	The northern is more pointed
„	11 58	„	Again doubtful

Madler referring to these and other observations of a similar character, in May and June 1836, expresses his opinion that they are quite irreconcileable with Bianchini's period of rotation, but may be compatible with the shorter one of Cassini and Schroter

THE MINOR PLANETS The following summary is founded upon elements of 153 members of this group which appear to be sufficiently well determined to afford reliable results. It exhibits the distribution of the perihelia, nodes, inclinations, and excentricities, and will be seen to offer several very decided characteristics

1 *Longitudes of the Perihelia*

	Number of Orbits		Number of Orbits
0 30	18	180 210	7
30 60	22	210 240	9
60 90	11	240 270	10
90 120	15	270 300	7
120 150	12	300 330	10
150 180	7	330 360	16

2 *Longitudes of the Ascending Nodes*

	Number of Orbits		Number of Orbits
0 30	15	180 210	19
30 60	13	210 240	8
60 90	17	240 270	5
90 120	6	270 300	7

A FREE SPANISH UNIVERSITY

OUR readers will easily understand what sort of foster mother a Government like that of Spain would prove to education generally and to scientific education and inquiry in particular Any educational institution connected with such a state must necessarily be hampered and hindered in many ways, and the only means of obtaining perfect liberty in scientific education and instruction is to be certain and free of all State interference This has been so strongly felt in Spain by some of the foremost Spanish ... that they have formed an association to found an institution for free education A prospectus of the institution has been forwarded to us, and the difficulties which beset a liberal education in Spain may be learned from the fact that it is signed by ten ex-professors of the high standing, all of whom have been removed from their chairs by Government on account of their liberal opinions Among them are the names of Augusto G de Linares, ex-Professor of Natural History at the University of Santiago, and Laureano Calderon, ex-Professor of Organic Chemistry at the same University The object of the Association, is stated in the prospectus is to found in Madrid a free institution dedicated to the culture and propagation of science in its various branches specially by means of education A sort of joint stock company will be constituted by shares of 250 francs, payable in four instalments between July next and April 1877 A preliminary meeting was to be held on the ... to constitute the Society, and we earnestly hope that a successful start has been made The Association will be directed by a Council representing all parties interested The Institution itself will, of course, be perfectly free from all religious, philosophical, or political restriction, the only principles being the 'inviolability of science' and the perfect liberty of teaching There will be established according to the circumstances and means of the Society (1) studies for general, secondary, and professional education with the academic advantages accorded by the laws of the State, (2) superior scientific studies, (3) lectures and brief courses, both scientific and popular, (4) competitions, prizes, publication of books and reviews, &c The greatest precautions will be taken to obtain as professors men of undoubted probity and earnestness and of the highest competence

We need say nothing to our readers in recommendation of the above scheme All who sincerely desire the welfare of Spain and the spread of scientific knowledge must sympathise with its promoters who, we have every reason to believe, are men of the highest character and competency We hope that not a few of our readers will show their sympathy with the object of the Association by sending the moderate subscription which constitutes a shareholder to M. Laureano Figuerola, Calle de Alcala 72, Madrid.

question naturally arises, Why is it not more frequently employed for practical purposes?

Unquestionably the first experiments with electric light were not successful, but this is generally the case with new inventions. Unfortunately, however, a feeling seems to have arisen directly against the application of electricity for lighting purposes, or at any rate against the employment of the existing apparatus in the hope that more perfect may soon be invented.

The numerous cases in which powerful electric lights

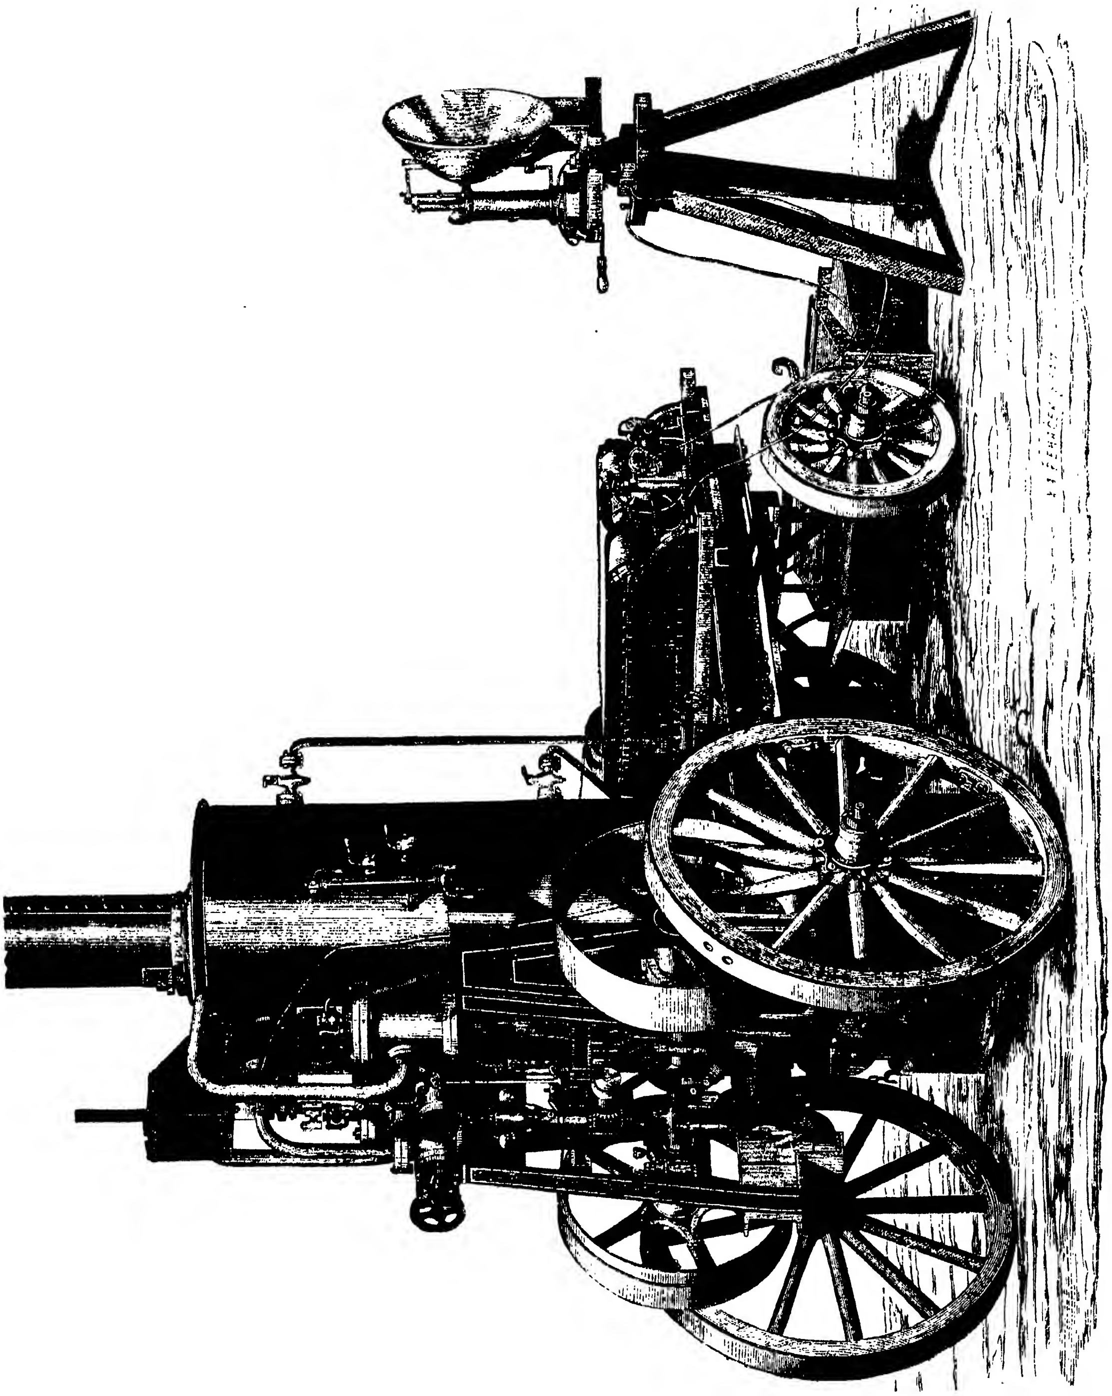

Fig. 1.—Dynamo-electric Light Apparatus with Portable Engine, Lamp, and Parabolic Reflector.

would be of service may be divided into two kinds: first those where a great number of lights are required at distant places, either simultaneously, or at intervals, and in varying numbers, such as lighting streets, extensive premises, &c. Second, those where only one or a few powerful lights are required, such as illuminating harbours and public places, as well as for lighthouses, signalling, and diving operations.

Great difficulty is experienced in properly adjusting the resistances and dividing the current, for the production of such a number of lights as is required in the cases of the first kind, and extensive experiments to overcome this difficulty have as yet been attended with only partial success

It is to those of the second kind that we purpose to draw attention Here the circumstances are quite altered, the cases of application are numerous, and the apparatus employed is perfect and proportionally cheap, and yet it is adopted not nearly so frequently as might be expected A constant light equal to that of from 9,000 to 10 000 stearine candles can easily be produced, with a motive force of from eight to nine horse power, and this at a cheaper rate than any other artificial light.

Such apparatus have lately been employed in various countries for various purposes, such as for engineering works, torpedo defences, signal lights, and in military field operations It is to be hoped that its adoption in this country will soon be more general

The following is a description of Messrs Siemens Electric Light Apparatus, one of many that have been adopted in various countries Comparative experiments have proved it to be the most powerful and at the same time the least expensive of all apparatus yet employed in the production of continuous electric light It is a complete apparatus by itself, in which the core of the armature is fixed and the wire helix alone caused to rotate By fixation of the armature core great inductive power is obtained, and consequently powerful currents

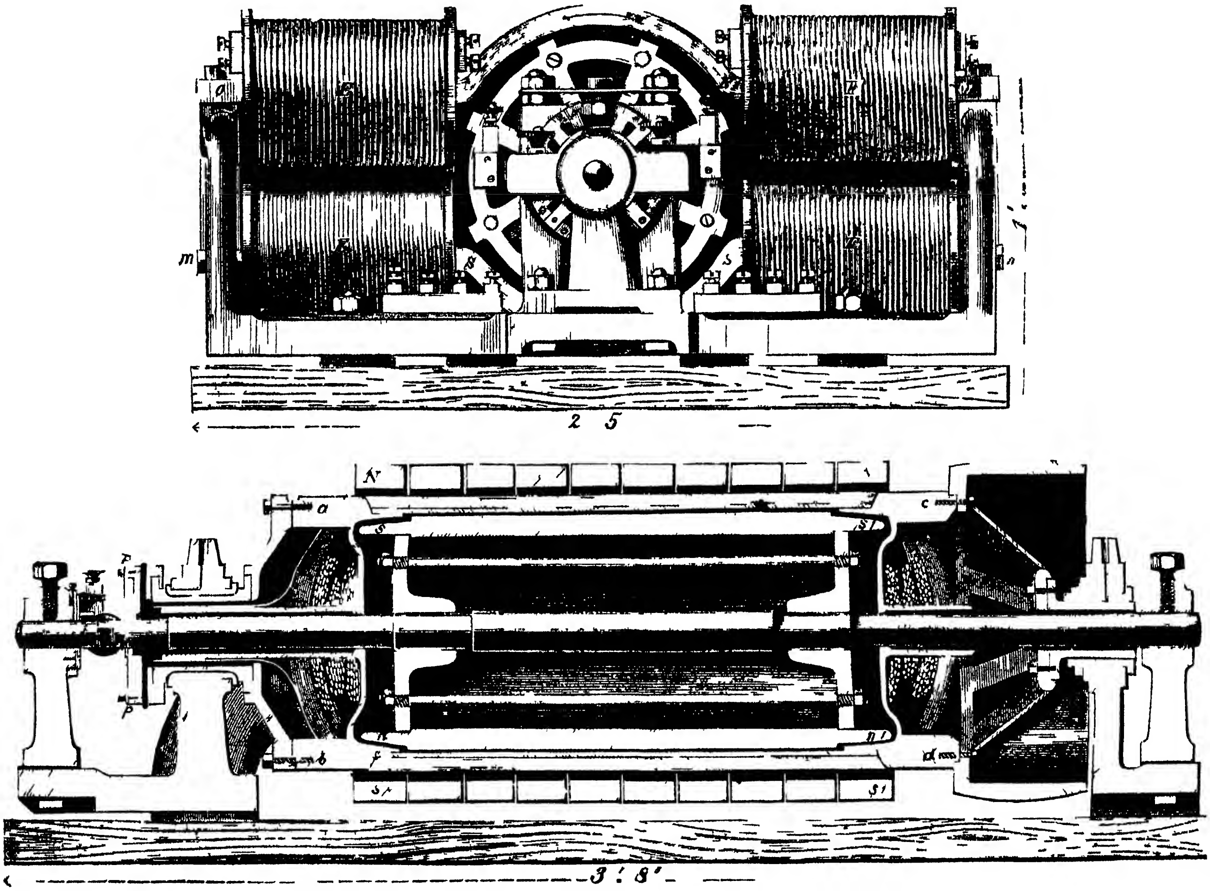

FIG 2 —End Elevation and Longitudinal Section of Dynamo electric Light Machine

With about 380 revolutions of the wire helix per minute, and nine to ten horse power, a light equal to 14,000 candles is obtained

The principle in this and all other magneto electric machines is, that when part of a closed electrical circuit is passed between the poles of a stationary magnet, a current is generated in the circuit the direction of which depends upon the position of the magnetic poles and direction of motion of the conductor.

In this machine (shown in Figs 1 and 2) the conductor, by the motion of which the electrical current is produced, is of insulated copper wire, coiled in several lengths, and with many convolutions on a cylinder of thin German silver, and in such a manner that each single convolution describes the longitudinal section of the cylinder. The whole surface of the metal cylinder is thus covered with wire, forming a second cylinder closed on all sides (*i*, *i*, *d*, Fig 2)

This hollow cylinder of wire incloses the stationary core of soft iron (*n s s n* Fig 2) which is fixed by means of an iron bar in the direction of its axis, prolonged at both ends through the bearings of the wire cylinder to standards Surrounding the wire cylinder for about two-thirds of its surface, are the curved iron bars (N N S S′ Fig 2), separated from the stationary iron core by space only sufficient to permit the free rotation of the wire cylinders The curved bars are themselves prolongations of the cores of the electro magnets (I F F I) and the sides of the two horse shoe magnets (N *o*—S, *m* and N *o*—S, *m*) are connected by the iron of the two standards (*i m* and *o m*)

As the coils of the electro-magnets form a circuit with

the wires of the revolving cylinder, the revolution of the latter causes a powerful current to pass into the electro-magnetic coils, this again inducing a still more powerful current in the wires of the cylindrical armature. The iron core of the cylindrical armature being very close to the poles of the electro-magnets, becomes itself an intensely powerful transverse magnet of opposite polarity to the electro-magnet. The cylinder of wire thus revolves in a very intense magnetic field.

These electrical currents are collected on two metal rollers or brushes, so that at two points diametrically opposite the single sectors pass under the rollers or brushes with elastic pressure giving up to them their electrical charge.

A slight increase of speed in the rotation of the wire cylinder is followed by a considerable increase of current, but as the current increases, so does the resistance to rotation; and this very rapidly. In addition to this heat is developed to such an extent, that care must be taken not to exceed a certain limit, otherwise, the insulation of the coils would be destroyed. Were it not for this drawback almost any amount of current might be produced with suitable driving power.

As the external resistance affects the strength of the current the speed must be varied accordingly, being greater as the external resistance is greater and *vice versa*. With an electric lamp in a circuit of small resistance, if the machine is intended to work continuously, the revolutions of the wire cylinder per minute should not exceed 370 to 380. The temperature of the machine will then be at a maximum in about three hours; and during work will remain constant. At this speed the driving power is about eight indicated horse-power. While the intensity of the light, unaided by reflector or lens, has been shown by various photometers to be equal to 14,000 normal English candles. A more intense electric light cannot be obtained as any increase in the current splits up even the best carbon.

The conducting wires from the machine to the lamp should be of copper, offering very little resistance and at the same time possessing a high electrical conductivity. If the lengths of the two wires do not together exceed fifty-five yards, then a wire of 0·157 inches diameter, and of high conductivity will suffice. For longer distances it is advisable to use a strand of larger diameter.

Increased speed will of course compensate for decrease of current due to a too great external resistance, but this can be done only at the expense of increased motive power.

The lamp used with the machine is regulated without clockwork, as the employment of the latter has not only been a source of numerous failures and difficulties, but is liable to disarrangement upon the least rough usage. The lamp of itself regulates the carbon points, keeping them at a uniform distance, and thus a perfectly steady light is produced.

For concentration either a parabolic reflector or a Fresnel dioptric lens may be used.

For transportation the Dynamo-electric Light Apparatus is mounted on a waggon, with steam-engine, the whole weighing 4,960lbs. The combination has proved very serviceable on account of its lightness and compactness.

THE ETHNOLOGY OF THE PAPUANS OF MACLAY COAST, NEW GUINEA[1]

WITH regard to the villages and dwellings. So thickly is the coast of Astrolabe Gulf covered with vegetation that no houses are visible to anyone on shipboard, the only signs of habitation being perhaps columns of smoke. If, however, more careful observation be made with a telescope, separate groups of cocoa nut palms will be noticed

[1] Continued from p. 109.

If a landing be effected near one such group, a *pirogue*, or canoe, will probably be seen drawn up on the shore, or else concealed in the jungle, and a path will be found leading through the wood to an open clearing, where stand huts overshadowed by bananas and cocoa-nut palms. Viewed from the side, one such hut seems almost wholly to consist of roof; as the side walls rise scarcely half a yard above the ground. A semi-circular eave-like projection frequently stands out over the doorway. Close in the neighbourhood of nearly every hut there stands upon four legs the *barla*, a kind of table or bench, which serves as the eating and resting-place of the men. Upon this, when the meal is ready, the host and his guests are seated, so that they can take their meal without fear of molestation from pigs or dogs. When the dishes are cleared away the Papuan takes his *siesta* upon the *barla*, which now serves as a kind of divan. The women on no account use the *barla*, but take their meals upon the ground. A village consists of several groups of huts (each group having a particular name) which stand around an open clearing, and communicate through narrow paths. The houses do not stand upon piles,[1] and are for the most part small and dark, though well and strongly built; the roofs in particular, which do not have a flatly-inclined surface, but bulge outside in order that the rain may be the easier carried off. The walls are made either of bamboo or of the stalks of sago-palm leaves. The door is raised generally about half a yard above the ground, to prevent the ingress of dogs and pigs.

There can generally be distinguished three kinds of hut—those of single people, those of families, and the [illegible], which is usually only used by men, being intended for the youths of the village, and any chance guest. Here will be remarked the [illegible],[2] a kind of gong, which plays so important a part in the life of the Papuans. It resembles a thick split beam resting upon two trestles, and on the middle of the outer side may be seen a smooth, much-worn patch, the place where it is hit with a very thick stick, by which is produced a dull but loud tone, which has been heard on the coast at as great a distance as five or six miles. All important events, *e.g.* the presence of an enemy, a death, or a feast, are by this instrument heralded to the neighbouring villages, the quality of the news being signified by the varying loudness of the tones produced, and the length of the pauses between each."

It is a most extraordinary fact that all the people of the coast here have no means at all of making fire; wherefore they are obliged always and everywhere to carry a live coal with them, be it either to kindle a fire in a plantation, or, when on a long tour in the mountains, to relight their cigars, which, being wrapped in green leaves, are always going out. On their sea voyages they have generally a live coal at the bottom of the boat, in a broken pot partly filled with earth. Those who remain behind in the villages never forget to look after the fire, and even in the night a small fire is kindled under the sleeping places, which partly makes up for scanty clothing. The warmth penetrates, together with smoke, through the interstices of the bamboo bedstead,[3] so that one-half of the sleeper's body is warmed, in fact roasted, while the other half is frozen. They are often obliged to get up in the night to see after the fire. The mountain people are not obliged thus to tend, like the priestesses of Vesta, an eternal flame, but understand how to kindle fire anew, and by the following method. A piece of very dry wood, which they term *Hol*, is split with a stone axe in such a manner that each half is not quite separated from the other. Into the fissure a strong cord, a split liana,

[1] The houses of all Malays, whether on the coast or in the mountains, always are built upon piles sometimes nine or ten feet long.—J. C. G.
[2] A similar instrument is figured in Schweinfurth's "Heart of Africa," as in use by the Niam-Niam tribe.—J. C. G.
[3] This is probably the equivalent of the *bali bali* of the Malays, a frame of split bamboo, raised slightly from the ground.—J. C. G.

in fact, is introduced, and, after that the piece of wood has been firmly pressed against the ground by the foot or knee, is put into a continually increasing frictional movement until some dry cocoa nut bark fibre, previously placed beneath, takes fire. This is a very tedious proceeding, as it lasts well nigh half an hour. The aborigines of the coast have repeatedly told Maclay that they are frequently obliged to go to other villages to procure fire when by chance the fires in all the huts of a village have gone out.

The Papuans pass most of their time outside their huts, these latter serving principally as shelter during the night, or in bad weather. To the tie-beam of the hut a cord is fastened, from which hangs a *mimu*, i.e. a stick with several hooks. In front of the stick a portion of the covering of the base of the leaf of the sago palm is so arranged that the cord passes through the middle of the same. To the hooks are hung various articles of food wrapped up in leaves. This arrangement serves to keep off the mice, which would otherwise make away with everything eatable in the night. Beyond a pair of spears, a few arrows, and other implements of the chase, there is nothing in the way of furniture in the hut of the Papuan. It would be difficult, in fact, to find a human habitation more meanly furnished. It is the custom to preserve [illegible] the lower jaw, of every animal which has been eaten at feasts. These [illegible] are hung around the walls of the large common hut—*[illegible]*.

The plantations, or gardens, of the Papuans are seldom [illegible] the huts, but for the sake of [illegible] are hidden [illegible]. A clearing is made by cutting down the [illegible] and after it has been dried in the sun, it is [illegible]. The place thus prepared is then surrounded by a kind of hedge consisting of two rows of a kind of [illegible] (*[illegible]*), which soon takes root, the opposite stems being fastened together with lianas, and the [illegible] space between the rows filled with rough hewn logs. In less than a month's time a new plantation is put in full order and planted with bananas, sugar cane, and the Colocasia and Dioscorea. The tools which are used for this purpose are very simple, being the *[illegible]*, a strong stick about two yards in length, and sharpened at one end—the implement of the men; and the *[illegible]*, which is used by the women, a kind of small spade. The Papuans have throughout the year a rotation of fruits and vegetables. Every day the women go forth to fetch from the plantations what is necessary for the same evening and the following morning. The coast people have the most property in cultivated land, while the islanders are chiefly employed in the manufacture of pots, dishes, and canoes.

Among the Papuans of Maclay Coast there exists neither trade nor a regular system of barter. If for instance, the coast people visit their neighbours or the people of the hills, or the islanders, they bring with them as a present all the superfluous articles which they possess, and on their departure receive as presents productions of the village which they have visited. Maclay has never seen one single present given or demanded in return for an equivalent gift.

Not many villages are in possession of *pirogues* (canoes), because most of those on the coast are situated in the neighbourhood of a surf so strong as to make landing impossible. The canoes are hewn out of a single tree-trunk, and have an outrigger (Aussengestell), and are manned by two rowers. The inhabitants, however, of Bili Bili and of the "Archipelago of Contentment," build larger canoes, provided with two masts, "taking" one fore, the other aft. In these canoes the aborigines can sail with the most unfavourable winds. The large sail consists of a pandanus[1] mat, and split bamboo and lianas serve as sheets and shrouds. The anchor is a piece of a tree trunk, of which four or five branches encircling it, after being cut short and sharpened to a point, serve as the "flukes," and is weighted by means of a number of stones attached to the shank by a sort of basket-work. Neither the coast people nor the inhabitants of the hills undertake voyages of any considerable extent.

With a few words on the daily life of the Papuans this article must be brought to a close. The Papuan of Maclay Coast marries early, and leads, morally speaking, a most model life, extra connubial alliances being seldom, or never, formed. The marriage settlements are very simple, the bridegroom making, on agreement with the bride's family, a few presents, such as dishes and dyed cloths. A few days after, a pig or a dog is slain, the marriage feast is celebrated, and the young man takes his bride off to his hut. There is a much simpler procedure, the event being marked by no feast, when a man divorces his wife because she is unable to work, perhaps on account of lameness, for he simply sends her off and takes another. In other respects the men treat their wives well, for it is very seldom that a wife is beaten. The women however, do all the hard work and carry heavy burdens, so that the freshness and healthiness of youth soon passes away. The children are very cheerful, and seldom scream. They are more petted by the father than by the mother, and Maclay has actually seen, what is very uncommon among savages, toys, in the shape of model canoes and a kind of top. They, however, in childhood learn all the pursuits of manhood, and early accompany their father into the plantations or on his fishing excursion. It is a comical, though not uncommon sight to see a boy of four years old gravely tend the [illegible], fetch wood, clean the dishes, help his father to peel fruit, and then, on the entrance of his mother, run to her and begin to take the breast. The women suckle for far too long a time, which, more than even overwork, is the cause of their having such small families. The day of the Papuan begins with the early dawn, and he loves the crow of the cock which heralds the approach of day. Even if he has nothing particular to do, off he goes to the shore, while it is yet dusk, enveloped in his *[illegible]*, and with chattering teeth awaits the sunrise. When his wife is already off to the plantation, he lingers over his breakfast, and then either chews betel or smokes a green cigar. About ten o'clock the men depart to their various occupations, and if a visit be paid to a village at noon, not a human being will be seen, but a dog or a pig or two will come out and inspect the intruder, and then disappear again. About four or five in the afternoon the men return, dripping from their daily bath. In spite of numerous skin diseases the Papuans can scarcely be termed dirty, for they daily, often several times a day, take a bath and rub their skin with sand or grass. Later on in the evening come their wives, sweating and staggering under their heavy burdens. Supper is then made ready. Into the *[illegible]* are emptied the most incongruous food stuffs, reminding us almost of the "ingredients" of the witches' caldron in "Macbeth," *e.g.* beetles, snails, crabs, caterpillars, and small lizards! On these colocasia or dioscorea are put and over all water, a third part being sea water, is poured, and the pot, covered with green leaves, is then set on the fire to boil. When all is ready, the master of the house distributes the portions, the worst morsels to his wife and children, reserving the best for himself and his guests. In order to obtain a *soupçon* of some flavour, the brine is drunk in which the food was cooked. After a cigar or a quantum of betel, the men retire to rest, previously taking care to light a fire under their bedsteads. So passes away the day of the Papuan, varied only by an occasional excursion, or a feast, or a preparation for war.

JOHN C. GALTON

[1] *Pandanus* is the generic term for the family of Screw palms.—J. C. G.

NOTES

THE first of the series of the free science lectures in connection with the Loan Collection of Scientific Instruments was given on Saturday evening at eight o'clock. The notice issued was but short, yet the room was not only as full as it could be, but the crowd was such that if space for 1,000 had been provided, all the places would have been occupied. The lecturer, as we announced, was Prof. Roscoe, and his subject was "Dalton's Instruments, and what he did with them." The following gentlemen have already volunteered to give their valuable assistance for future lectures, which will take place on Monday, Tuesday, and Saturday evenings at 8 o'clock:—Prof. F. A. Abel, F.R.S., President of the Chemical Society, Capt. Abney, R.E., F.R.S., Prof. Roscoe, F.R.S., Dr. Warren De la Rue, F.R.S., Prof. G. Carey Foster, F.R.S., President of the Physical Society, Dr. J. H. Gladstone, F.R.S., Prof. Guthrie, F.R.S., Mr. J. Baillie Hamilton, Mr. Norman Lockyer, F.R.S., Rev. R. Main, M.A., F.R.S., the Right Hon. Lord Rayleigh, F.R.S., Dr. W. J. Russell, F.R.S., Mr. W. Spottiswoode, M.A., F.R.S., Dr. W. H. Stone, Rev. S. J. Perry, F.R.S., the Right Hon. Lyon Playfair, M.P., F.R.S., the Right Hon. the Earl of Rosse, F.R.S., Mr. C. V. Walker, F.R.S., Mr. W. C. Roberts, F.R.S., Mr. W. H. Preece. The next lecture will be given on Saturday evening by Prof. Guthrie, On Cold; on Monday the Rev. S. J. Perry will lecture On the Transit of Venus Instruments. It is proposed to give the following demonstrations on Saturday, Monday, and Tuesday next:—11 A.M., Marine Engines in Motion; 11.30, Fog Horns, Electric Light, Spectrum of Electric Light; 12.45 P.M., Time Gun; 1.30, Radiometers; 2 to 5, Pictet's Ice-making Machine; 2.30, Orreries; 3, Sir J. Whitworth's Millionth Measuring Machine and True Planes (Monday only); 3.30, Electric Light, Musical Instruments (Monday only), Ancient Musical Instruments (Tuesday only); 4.30, the *Times* Type-Composing Machine; 7.30, Telegraphic Apparatus (Monday and Tuesday only); 8, Sir J. Whitworth's Machines (Monday only); 8 to 9, Little Basses' Lighthouse; 8, Lecture in Conference Room (Saturday and Monday). In the list of papers read on Tuesday week we omitted to mention those of Dr. C. B. Fox, "On the Employment of Aspirators in Atmospheric Ozonometry," and Mr. J. Allan Broun "On Barometric Variations and their Causes." On Thursday, besides the papers already mentioned, Dr. Rae made a communication on Arctic Maps. On Friday Mr. W. S. Mitchell read a paper on the MS. tables and maps of William Smith. On Whit Monday 11,964 people visited the Collection; on Tuesday the number was 5,656.

AT the meeting of the American Academy of Science, on March 8, the president, Hon. Charles Francis Adams, presented the Rumford medals (in gold and silver) to Dr. John W. Draper, for his researches in radiant energy. In presenting the medals, the president alluded, among other matters, to Dr. Draper's discovery, in 1840, of the peculiar phenomena commonly known as Moser's images, to his method of measuring the intensity of the chemical action of light, afterwards perfected and employed by Bunsen and Roscoe in their investigations, and especially to his elaborate investigation, published in 1847, in which Dr. Draper established experimentally several important facts in spectrum analysis.

ON Thursday, June 1, M. Dumas, the eminent chemist, delivered his inaugural address, as the new member of the Académie Française. M. Dumas read in a clear and impressive tone. His task was to deliver an *éloge* on M. Guizot, whose career touched science at very few points. M. Dumas accomplished his duty with perfect tact, and used language which his hero would have wholly approved.

AT a meeting recently held in Sydney it was resolved to obtain subscriptions to enable Signor D'Albertis to carry out a scheme for the exploration of New Guinea. This well-known naturalist and explorer proposes to ascend the Fly river to the centre of the island, where very probably the river has its sources, and to find his way back by land to Yule Island or Port Moresby. The journey altogether will probably last from eight to twelve months, and he would require a steam-launch, 35 or 40 feet long, with furnaces for burning wood, besides a small contingent of men. He will obtain all possible information as to the geography, fauna, flora, and mineralogy of the district traversed. Signor D'Albertis offers himself to subscribe at least 200*l*. to the expedition. The New South Wales Government, we are glad to see, has put the steam-launch *Neva* at Signor D'Albertis' disposal, and we have no doubt that by this time the very moderate sum required has been subscribed.

SIR JOSEPH WHITWORTH was on Thursday last presented with the freedom of the Turners' Company.

AT the last meeting of the Lisbon Commercial Association it was proposed to ask the Government to send an expedition to carry out Lieut. Cameron's projects, starting from Angola. The suggestion was made that scientific men should accompany the expedition.

THE President and Council of the Geological Society hold a reception on Saturday evening at the Society's rooms, Burlington House.

AMONG the passengers in the mail steamer *Artuasus*, which sailed from Leith on the 2nd inst. for Iceland, are Prof. Jonstrup, M. Fieldberg, surveyor, and M. Gronlund, botanist. On arriving at Iceland these gentlemen are to be joined by Lieut. Njdal, of the Danish gunboat on the station, and an expedition is to be formed to proceed to the scene of the recent volcanic eruption.

ON Saturday afternoon the annual meeting of the Board of Visitors of the Royal Observatory, Greenwich, was held, at which the report of the Astronomer Royal, Sir G. B. Airy, was read.

REGULAR courses of lectures have been established at the Naval Observatory, Montsouris, for the officers of the French national navy attached to the establishment. The general principles of Astronomical Observations are lectured upon by M. Loewy; Special Naval Methods, by Capt. Turquet, the Director of the establishment; Terrestrial Magnetism, by M. Marié Davy, Director of the Montsouris Observatory; Spectroscopy, by M. Cornu; Photography in its Application to Astronomy, by M. Angot, of the National Observatory of Paris. All the observations made by the pupils are submitted to correction, and will be utilised as far as possible for the improvement of *Connaissance des Temps*.

THE Municipal Council of Paris voted some time since money for organising a number of meteorological observatories, to be modelled after the Montsouris pattern, and to be located in the several districts of Paris. The Prefect of the Seine has appointed a Commission, to organise these observatories on the top of several public buildings, divided as far as possible from among the several districts.

A TESTIMONIAL was recently presented at Wisbech to Mr. S. H. Miller, F.R.A.S., F.M.S. The testimonial, subscribed for by a large number of gentlemen in the district, is of the value of about 100*l*., and the inscription on the plate states that it is "presented as some acknowledgment of the value of the services he has rendered to the interests of education, science, and agriculture."

The French Senate and the French Chamber of Deputies, are both of them busy with educational matters. The Government has proposed to the Senate to restore the National Institute of Agriculture, which had been established at Versailles by the second Republic but was abolished by the Empire. The Chamber of Deputies has voted, after a very interesting address delivered by M. Waddington, the Minister for Public Instruction, the first reading of a Bill restoring to the Government the right of appointing examiners for granting honours to the pupils of the so-called Free Universities.

The volume of the *Zoological Record* for 1874 has just reached us. Under the editorship of Mr. E. C. Rye, Librarian to the Royal Geographical Society, Mr. E. R. Alston has undertaken the Mammals, Mr. R. B. Sharpe and Dr. Murie the Birds, Mr. O'Shaughnessy the Reptiles and Fish, Prof. E. von Martens the Molluscs and Crustacea, Rev. O. P. Cambridge the Arachnida, Mr. Rye the Myriapoda and Insects, whilst Dr. C. F. Lütken has taken the lower Invertebrata. Mr. Rye acknowledges a grant of 100*l*. from the British Association and 50*l*. from the Zoological Society towards the expenses of the *Record*.

The Watford Natural History Society now numbers 170 members of all classes.

The conductors of the Botanical Locality Record Club have shown themselves amenable to criticism, and have rendered their proceedings much less obnoxious to the objection at one time raised against them, that they were doing their best to promote the extirpation of rare plants. Their Annual Report for 1875, just issued, is a valuable publication. It is divided into five parts. In the first division they give new "County Records" of various species and sub-species, very few special localities being given; in the second, a "General Locality List," including all observations of interest made during the year; in the third, a list of "Extinctions, Reappearances, and Confirmatory Records;" in the fourth, a list of "Aliens, Casuals, and Escapes;" in the fifth, "County Catalogues of Plants;" those in the present month being Merioneth and Montgomery and Stirling. In the case of three counties, North Lincoln, Stirling, and Roxburgh, there is in the present Report an addition of upwards of fifty species of flowering plants and Vascular Cryptogams to those previously recorded. The divisions of counties are those adopted by Mr. H. C. Watson. There ought soon to be but little addition possible to our knowledge of the distribution of British plants.

During the coming summer (July and August) opportunity will be given at Cincinnatti Observatory, University of Cincinnati, for the study of Higher Analysis, Spherical and Practical Astronomy, and Celestial Mechanics. These advantages are intended, primarily, for teachers who may desire to spend their vacation in the pursuit of studies connected with their own work. Special attention will be paid to the art of computing, in order to give an insight into the practical application of mathematics to astronomy. Opportunity will also be afforded to learn the use of instruments. The Americans certainly seem to be ahead of us in the opportunities they devise for varied practical scientific work.

Messrs. Jarrold and Sons will shortly publish "Rambles of a Naturalist in Egypt and other Countries," by Mr. J. H. Gurney, jun.

On the 29th and 30th inst. an interesting trial of the sagacity, activity, and docility of Collie dogs will take place at the Alexandra Palace. The dogs will be tried successively in the management of one hundred Welsh wethers.

To those of our readers who are fond of either the rod or the gun, and who intend to spend their holidays in Scotland, we strongly recommend Mr. Watson Lyall's "Sportsman's and Tourist's and General Guide to the Rivers, Lochs, Moors, and Deer Forests of Scotland." It contains a vast amount of information, including frequent details as to the natural features and objects of antiquarian interest in the various districts. Those who cannot take a holiday will be quite refreshed by an occasional dip into it at the season when "everybody" is supposed to be out of town. A special large-scale extremely well-constructed map of Scotland accompanies the "Guide," as also a map of England.

Bentley and Trimen's "Medicinal Plants" has now advanced as far as the seventh part. Each part contains seven or eight coloured plates, with full descriptions of plants which are officinal in the pharmacopœias of England and the United States. The quality of both letter-press and figures is well maintained; and when complete the work will be an absolutely indispensable one to the pharmacologist.

"The Work and Problems of the Victoria Cave Exploration" is the title of an interesting paper read recently by Mr. R. H. Tiddeman before the Geological and Polytechnic Society of the West Riding of Yorkshire. It is printed by McCorquodale and Co., Leeds.

A work entitled the "Anatomia dell' Ape," by Clerici, has been recently published at Milan under the auspices and special supervision of the Central Italian Bee-keepers' Association. This highly interesting publication consists of a series of thirty beautiful chromo-lithographic plates, 8 inches wide by 12 inches high, artistically produced, with admirable frontispiece for binding. We understand that the execution of this anatomical work his occupied considerable time, and that prizes have been awarded to it at the Vienna Exhibition and elsewhere. In connection with this we may note the receipt of a useful little "Manual of the Apiary," by Mr. A. J. Cook, of the Michigan State Agricultural College.

We are glad to see from the 62nd Annual Report of the Royal Geological Society of Cornwall that that Society continues to be prosperous and useful.

The Twenty-Second Annual Report of the Brighton and Sussex Natural History Society, which is in a prosperous condition, contains the following among other papers:—"On Recent Excavations at Cissbury," by Mr. Ernest Willett; "On Wingless Birds," by Mr. T. W. Wonfor; "What is a Brachiopod?" by Mr. T. Davidson, F.R.S.; and on "The Birds and Mammals of Sussex," by Mr. F. E. Sawyer.

An English translation has been published of Lieut. Weyprecht's admirable address given at Graz last September, on the "Fundamental Principles of Arctic Exploration," of which we gave an abstract at the time. We believe it may be obtained in London from Trübner and Co.

The additions to the Zoological Society's Gardens during the past week include an Ocelot (*Felis pardalis*) from Para, presented by Mr. W. A. Sumner; a Vulpine Phalanger (*Phalangista vulpina*) from Australia, presented by Mr. C. H. A. Forbes; four Fawn-coloured Field Mice (*Mus cervicolor*) from India, presented by Col. C. F. Sturt; a Blue Jay (*Cyanocitta cristata*) from North America, a Chinese Jay Thrush (*Garrulax chinensis*) from China, presented by Mr. E. Hawkins; two Barnard's Parrakeets (*Platycercus barnardi*) from Australia, deposited; a White-throated Capuchin (*Cebus hypoleucus*) from South America, a White-bellied Sea Eagle (*Haliaetus leucogaster*) from Australia, a Derbian Screamer (*Chauna derbiana*), two Green-billed Curassows (*Crax viridirostris*), a Red-billed Tree Duck (*Dendrocygna autumnalis*) from Cartagena, purchased; a Bonnet Monkey (*Macacus radiatus*), born in the Gardens.

LOAN COLLECTION OF SCIENTIFIC APPARATUS

SECTION—MECHANICS

PRIME MOVERS

THE subject on which I have now the honour to address you, the subject which is to occupy our attention to-day, is that of prime movers, that is to say, we are about to consider that class of machines which, to use the words of Tredgold, "enable the engineer to direct the great sources of power in nature for the use and convenience of man."

Although machines of this kind are, in truth, mere converters or adapters of extraneous forces into useful and manageable forms, and have not any source of life, power, or motion, in themselves, nevertheless they impress us with the notion of vitality; and it is difficult to regard the revolving shaft of a water-wheel or turbine, set in motion by some hidden stream, or to gaze upon the steam-engine actuated by an unseen vapour, without, as I have said, the idea being raised in our minds that the machines on which we are looking are really endowed with some kind of life.

The invention of such machines marks a very great step in the progress of mechanical science in the world, as it commences an era distinct from that in which mere machines to be acted on by human or animal muscular force were alone in existence. Machines such as these, highly useful as they may be, are, after all, only tools or implements more or less ingenious and more or less complex.

Mankind could not have been very long upon the earth before they must have found the need and must have discovered the utility of some kind of tool or implement; they must soon have found that the direct action of the power of the arm, which was not enough by itself to break up some obstacle, became sufficient if that action were applied by the wielding of a heavy club, or through the putting into motion of a large stone, and thus the hammer or its equivalent must have been among the earliest of inventions. Such an implement must soon have taught its users that muscular force could be exercised through a considerable space, could be stored up, and could be delivered in a concentrated form by a blow.

Similarly it could not have been long before it must have been found that to raise water in the hollow of the hand by repeated efforts was not so convenient a mode as to raise it in a bent leaf or in a shell, and in this way another implement would speedily be invented. We might pursue this line of speculation, and doing so we should readily arrive at the conclusion that (without attributing to the early inhabitants of the earth any profound acquaintance with mechanics) the hammer, the lever, the wedge, and other simple tools and utensils, must soon have come into existence; and we should also be led to believe that when, even with the aid of tools such as these, a man singly could not accomplish any desired object, the expedient of combining the power of more than one man to attain an end would soon be thought of, and that the requisite appliances, such as large beams used as levers, numerous ropes (which must very early in the history of the world have been twisted from filaments) and matters of that kind, would come into use. For a corroboration of this view, if one were wanted, the fact may be cited that on the discovery of any isolated savage community it always is found to have advanced thus far in mechanical art.

But passing from such machines as these, which are rather of the character of tools and implements, than machines, as we now popularly use the word, one knows that even complicated mechanism for the purpose of enabling muscular force to be more readily applied, is of very ancient date. On this point I will quote from only one book, that is the Bible, where, at the 10th and 11th verses of the 11th chapter of Deuteronomy, a statement is made clearly indicating that in Egypt irrigation was carried on by some kind of machine worked by the foot; whether the treadwheel with water-buckets round about it mentioned by Vitruvius, or whether the plank-lever with a bucket suspended at one end and worked by the labourer running along the top of the lever to the other end (an apparatus even now used in India), we do not know; but that it was some machine worked by the foot is clear, the statement being that when the Israelites had reached the Promised Land they would find it was one abounding in streams, so as to be naturally watered, and that it would not require to be watered by the foot as in Egypt. Again, in Chronicles it is related that King Uzziah loved husbandry, and that he made many engines, unhappily not in connection with agriculture, but for warlike purposes, "to shoot arrows and great stones withal." Further, in the 7th chapter of the Book of Job, we have the comparison of the life of man passing away swifter than a weaver's shuttle; this points unmistakeably to the fact that there must in those days have been in existence a loom capable of weaving fabrics of such widths that the shuttle required to be impelled with a speed equal to a flight from one side of the fabric to the other, and no doubt such a fabric must have been made in a machine competent at last to raise and depress alternately the halves of the warp threads. The potter's wheel also is frequently mentioned in the Bible.

Such instances as these are sufficient to show that considerable progress must have been made in the very earliest days of history in the construction of machines whereby muscular force was conveniently applied to an end; but if we leave out of account, as we fairly may, the action of the wind in propelling a boat by sails, and the action of the wind in winnowing grain, I think we shall be right in considering that in the times of which I have been speaking there did not exist any machine in the nature of a power-giver or prime mover.

Doubtless the want of a greater force than could be obtained from the muscles of one human being must have soon made itself felt; and intelligent men, conscious of their own ability and of their mental power of directing a large amount of work, must have been grieved at finding the use of that power circumscribed by the limited force of their own bodies, and therefore early in the world's history there must have been the attempt, by the offer of some consideration or reward, to induce other men (men gifted with equal or stronger muscles, but probably not with equal minds) to work under the directions of these men of superior intelligence. But when such aid as this became insufficient, the way in which, in all probability, the people of those days endeavoured to satisfy the further demand would be to make captives of their enemies and to reduce them into a state of bondage, to grind at the mill, to raise water, or, yoked by innumerable cords and beams to some heavy chariot or sledge, to draw along the huge blocks required in the foundations of a temple, or for the building of a pyramid, or to act in concert on the many oars of a galley, although by what means this last-named operation was performed is not very clear. Doubtless under this condition of things there must have been an amount of human suffering which is too frightful to be contemplated.

Such machines as those to which I have called attention could not have been invented and brought into use without the exercise of much mechanical skill; but considerable as this skill must have been it had never originated a prime mover; it had given no source of power to the world, but had left it dependent on the muscular exertions of human beings and of animals.

Great, then, was the step, and a most distinct era was it in mechanical science, when for the first time a prime mover was invented and a machine was brought into existence which, utilising some hitherto disregarded natural force, converted it into a convenient form of power, by which as great results could be obtained as were obtainable by the aggregation of a large number of human beings, and could be obtained without bondage and without affliction.

There are probably few sights more pleasing to one who has been brought up in factories than to watch a skilful workman engaged in executing a piece of work which requires absolute mastery over the tools that he uses, and demands that they should have the constant guiding of his intelligent mind. Handicraft work of such a kind borders upon the occupation of the artist, and to see such work in the course of execution is, as I have said, a source of pleasure. But when descending from this the work becomes more and more of the character of mere repetition, and when it is accomplished by the aid of implements which, from their very perfection require but little mind to direct them, and demand only the use of muscle, then, although the labour, when honestly pursued, is still honourable, and therefore to be admired, there comes over one a feeling of fear and of regret that the man is verging towards a mere implement. But when one sees, as I have seen in my time, in England, and as I have seen very recently on the Continent, men earning their living by treading within a cage to cause it to revolve and thereby to raise weights, an occupation demanding no greater exercise of intelligence than that which is sufficient to start, to stop, and to reverse the wheel at the word of command, one does indeed regret to find human beings employed in so low an

[1] Address delivered by F. J. Bramwell, C.E., F.R.S., one of the vice-presidents of the Section, May 25.

occupation, an occupation that places them on a level with the turnspit. It is one which is most properly meted out in our prisons as a punishment for crime, accompanied, however, with the degradation that the force exerted shall be entirely wasted in idly turning a fan in the free air, and thus the prisoner, in addition to the fatigue of his body, undergoes the humiliation of, as he expresses it, "grinding the wind."

If they played no other part than that of relieving humanity from such tasks as these, prime movers would be machines to be hailed.

True it is that the labourers who were thus relieved would not thank their benefactors, and indeed so far as the individuals subjected to the change were concerned they would have cause not to thank them, because they having been taught no other mode of earning a livelihood, and finding the mode they knew set on one side by the employment of a prime mover, would be at their wit's end for a means of subsistence, and would be experiencing those miseries which are caused by a state of transition. But in some way the men of the transition state must be relieved, and in the next generation, it no longer being possible to subsist by such wholly unintelligent labour, the energies of their descendants would be devoted to gaining a livelihood by some occupation more worthy of the mind of man.

Early prime movers, from their comparatively small size, probably did little more than thus relieve humanity; but when we come to consider the prime movers of the present day, by which we are enabled to contain within a single vessel and to apply to its propulsion 8,000 indicated horse-power, or an equivalent of the labour of nearly 50,000 men working at one time, we find that the prime mover has another and most important claim upon our interest: it enables us to attain results that it would be absolutely impossible to attain by any aggregation of human or other muscular effort, however brutally indifferent we might be to the misery of those who were engaged in that effort.

Excluding from our consideration light and even electricity, as not being, up to the present time, sources of power on which we rely in practice, there remain three principal groups into which our prime movers may be arranged, viz., those which work by the agency of wind, those which work by the agency of water, and those which work by the agency of heat. But some of these great groups are capable of division, and indeed demand division into various branches.

Water power may be due to the impact of water, as in some kinds of water-wheels, turbines, and hydraulic rams, or to water acting as a weight or pressure, as in other kinds of water-wheels, and in water-pressure engines; or to streams of water inducing currents, as in the case of the jet-pump, and of the "Trombe d'eau," or to its undulating movements, as in ocean waves. The ability of water to give out motive force may arise from falls, from the currents of rivers, from the tides, or, as has been said, from the oscillation of the waves.

Prime movers which utilise the force of the wind are few in number and in all cases act by impact.

As regards those prime movers which work by the aid of heat, we may have that heat developed by the combustion of fuel, and being so developed applied to heating water, raising steam, and working some of the numerous forms of steam-engines; or, as in the case of the Giffard injector, performing work by induced currents, by the flow of steam; or we may have the heat of fuel applied to vary the density of the air, and thus to obtain motion as by the smoke-jack; or the fuel may be employed to augment the bulk and the pressure of gases, as in the numerous caloric engines; or we may have heat and power developed in the combustion of gases, as in the forms of gas-engines; or in the combustion of explosives, as in gunpowder, dynamite, and other like materials, used not only for the purposes of artillery and of blasting, but for actuating prime movers in the ordinary sense of the word.

Again, we may have the heat of the sun applied through the agency of the expansion of gases or surfaces to the production of power, as in the sun-pumps of Solomon de Caus and of Belidor, and as in the sun-engine of Erricsson. Finally, we may have the sun's rays applied direct, as in the radiometer of Mr. Crookes.

A consideration of the foregoing heads, under which prime movers range themselves, will speedily bring us to the conclusion that the main centre of all mechanical force on this earth is the sun. If the prime movers be urged by water, that water has attained the elevation from which it falls, and thus gives out power by reason of its having been evaporated and raised by the heat of the sun. If the power of the water be derived from the tidal influence, that influence is due to the joint action of the sun and the moon.

If the prime mover depend upon the wind for its force either directly, as in windmills, or indirectly, as in machines worked by the waves, then that wind is caused to blow by variations of temperature due to the action of the sun. If the prime mover depend upon light or upon solar heat, as in the case of the radiometer and of the sun engine, then the connection is obvious; but if the heat be due to combustion, then the fuel which supports that combustion is, after all, but the sun's rays stored up. If the fuel be, as is now sometimes the case, straw or cotton stalks, one feels that they have been the growth of the one season's effect of the sun's rays. If the fuel be wood, it is equally true that the wood is the growth of a few seasons' exercise of the sun's rays, but if it be the more potent and more general fuel coal, then, although the fact is not an obvious one, we know that coal also is merely the stored up result of many ages exercise of solar power.

And even in the case of electrical prime movers, these depend on the slow oxidation, that is burning, of metal which has been brought into the metallic or unburnt state from the burnt condition (or that of ore) by the aid of heat generated by the combustion of fuel.

The interesting lecture-room experiment with glass tubes charged with sulphide of calcium, or other analogous sulphides, makes visible to us the fact that the sun's rays may be stored up as light; but that they are as truly stored up (although not in in the form of light) in the herb, the tree, and the coal we also now know; and we appreciate the far-seeing mind of George Stephenson who astonished his friend by announcing that a passing train was being driven by the sun. We know that Stephenson was right, and that the satirical Swift was wrong when he instanced as a type of folly the people of Laputa engaged in extracting sunbeams from cucumbers. The sunbeams were as surely in the cucumbers as they are in the sulphide of calcium tubes, but in the latter case they can be seen by the bodily eye, while in the former they demand the mind's eye of a Stephenson.

Although the sailing of ships and the winnowing of grain must from very early time have made it clear that the wind was capable of exercising a moving force, nevertheless, being an invisible agent, it is not one likely to strike the mind as being fit to give effect to a prime mover, and therefore it is not to be wondered at that prime movers actuated by water are those of which we first have any record, unless indeed the toy steam-engine of Hiero may be looked upon as a prime move anterior to those urged by water. It would appear that in the reign of Augustus water-wheels were well known, for Vitruvius, writing at that time, speaks of them as common implements, but not so common as to have replaced the human turnspit, as we gather from his writings that the employment of men within a treadwheel was still the most ordinary mode of obtaining a rotary force. It would seem, however, that water-wheels driven by the impact of the stream upon pallet boards were employed in the time of Augustus not merely to raise water by buckets placed about the circumference of the wheels, but also to drive millstones for grinding wheat, and Strabo states that a mill of this kind was in use at the palace of the King of Pontus.

(To be continued.)

SCIENTIFIC SERIALS

Poggendorff's Annalen der Physik und Chemie, No. 2, 1876.—In the opening paper of this number Dr. Konig describes a series of researches in which he sought to study more closely the phenomena which occur when two sets of sound-waves meet in air; using sources of sound that were entirely isolated and could not act directly on each other, nor in common on a third body; he also chose sources that would give as simple tones as possible. The paper is in four parts, treating, severally, of primary beats and beat-tones, secondary beats and beat-tones, difference-tones and summation tones, and the nature of beats and their action, compared with the action of primary impulses. On the last head he finds, *inter alia*, that beat-tones cannot be explained by the cause of difference and summation tones, and that the audibility of beats depends only on the number and intensity of the primary tones, not at all on the width of the interval. The number of beats and primary impulses with which both may be

perceived as separate impulses is the same; so, too, with the number at which beats and primary impulses pass into a tone. Intermittences of a tone, as well as beats and primary impulses, may pass into a tone, and the periodic maxima of vibration of a tone, when in sufficient number. The beat tone formed by two primary tones must be always weaker than these, though separate beats are stronger than the tones forming them.—In M. Grotrian's researches on the constants of friction of some salt solutions, and their relations to galvanic conductivity, the method for ascertaining the constants was that of observing the oscillations of a suspended disc with attached magnet (under the influence of a neighbouring magnet) in air and in the liquid examined. The observed generally similar course of temperature coefficients for fluidity and galvanic conductivity, with change of concentration, leads the author to conclude that the overcoming of internal friction forms an essential part of the work done by a current in passage through an electrolyte. In the case of chloride of potassium, it is found that the increase of conductivity is almost exactly proportional to the per-centage proportion (in the liquid); and M. Grotrian infers that the chemical changes he conceives generally to occur in chemical constitution of electrolytic molecules, on altering the concentration, do not occur here, but that with varied concentration, at the same temperature, the conductivity is only conditioned by the proportion of salt and the viscosity. With the numbers obtained in the experiments, it is possible to estimate for variously concentrated solutions of a salt, the temperatures for which the constants of friction have some determinate constant value; then to calculate the numbers for the conductivity at this temperature, and inquire according to what law these alter with the concentration. He thus shows that in the case of NaCl, KaCl, $CaCl_2$, and $BaCl_2$, the concentration and the viscosity are the principal factors which determine the amount of the conductivity.—In the next paper M. Wiedemann makes some adverse criticism on the recent researches of some French physicists in the domain of magnetism.—M. Holtz shows that wire-net is very well suited for proving that in the interior of conducting surfaces there is no electrostatic action. In one experiment, a bell-shaped cover, made of the net, is brought down by an insulating handle on an insulated metallic disc connected with an electric machine, and on which stands a pith-ball electrometer. The two balls do not diverge in the least on working the machine; but if the bell be removed, they do so at once. He shows further, how such a bell is like a filter or sieve, holding back the electricity while it affords partial passage to gaseous matter or dust. If a metallic point connected to earth be brought near the electrified bell, the balls are moved, but do not diverge, &c.—Dr. Wichmann studies the properties of doubly-refracting garnets; and we note a paper by Dr. Sohncke on the figures eaten out by dissolving liquids on blocks of rock salt, and Exner's method for producing solution-figures.—There is an account of an interesting inquiry, lately conducted by Dr. W. Siemens, on the velocity of propagation of electricity in suspended wires.

Proceedings of the Geological and Polytechnic Society of the West Riding of Yorkshire. New Series. Part 2. Pp. 57 to 112.—This part contains several very interesting papers on various points of local geology. Some of the papers will be of use to a wide circle of readers, such as Mr. C. Bird's on the red beds at the base of the carboniferous limestone in the north-west of England, and Prof. Green's on the variations in thickness of the Silkstone and Barnsley coal seams in the southern part of the Yorkshire coalfield, and the probable manner in which these and similar changes have been produced. Mr. Bird considers it better to regard the red beds in question as basement beds of the carboniferous limestone than to attempt to draw any arbitrary line in a series whose members appear so closely linked together. Mr. Tiddeman's concise account of the work and problems of the settle Victoria cave exploration will also be welcome. Five good plates accompany this number of the *Proceedings*.

Bulletin de l'Academie Royale des Sciences, 2 ser. tome 40, No. 12.—M. van Beneden contributes a long paper divided into six chapters on the early stages of the embryological development of mammals. In 1874 M. Beneden published his paper, in which he showed that in Hydractinia spermatozoids are derived from the ectoderm and ova from the endoderm. He suggested that the same law probably applied to vertebrata. Observations supporting his view with regard to Cœlenterata have been made by Koch and Fol, and M. Beneden has made embryological studies on the rabbit. A monograph with plates is promised. This paper is a *résumé*.—On the skeleton of a fossil whale in the museum at Milan, by P. J. van Beneden. Following up the descriptions of Pachyacanthus and Aulocetus already given, M. Beneden proceeds to describe the fossil found in 1806 at Mount Pulgnasco, preserved in the Milan Museum, figured by Cortesi and described by Cuvier. The description is accompanied by a plate, and there are references to fossil whales in the museums at Turin, Florence, Bologna, Parma, and Pisa.—On the period of cold of the month of December, 1875, by M. E. Quetelet.—On the Devonian sandstones of Condroz, in the Basin of Theux, in the basin between Aix-la-Chapelle and Ath, and in the Boulonnais. The paper is illustrated with a folding plate giving nine coloured sections, and its scope is to show that the beds of the different localities mentioned have the same relative stratigraphical relations as at Condroz. All of the subdivisions show a remarkable constancy in their petrological and palæontologica aspects.—On the description of some new birds, by M. Alph. Dubois. They belong to Cyanscitta and Icterus.—The theory of carnivorous and sensitive plants, by E. Morren. The article is a *résumé* of observations that have been made, and is well furnished with foot-notes. The index accompanies this number.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, May 18.—"Observations on Stratified Discharges by means of a Revolving Mirror, by William Spottiswoode, M.A., Treas. R.S.

In a paper published in Poggendorff's *Annalen*, Jubelband, p. 32, A. Wüllner has described a series of observations made, by means of a revolving mirror, upon the discharge of a large induction-coil through tubes containing ordinary atmospheric air at various degrees of pressure.

Wüllner's observations appear to have been directed rather to the nature of the coil discharge than to that of the stratifications.

For some time prior to the publication of the volume in question I had been engaged upon a series of experiments very similar in their general disposition, but with a somewhat different object in view, viz., the character and behaviour of the striæ; and of these, together with some recent additions, I now propose to offer a short account to the Society.

My general instrumental arrangements appear to have been similar to those of Wullner; in fact, they could hardly have been very different. The tubes were attached to the coil in the usual way, and a contact-breaker of the ordinary form with its own electro-magnet was in the first instance used. For this and some other intermediate forms there was finally substituted a mercurial break (successfully arranged by my assistant, Mr. Ward), the plunger of which works on a cam attached to the axle of the mirror, so that the action of the contact-breaker is regulated by that of the mirror, instead of the reverse as in the former arrangement. With the broader tubes a slit was used; with the narrower this adjunct was less necessary; while with capillary tubes, such as are used for spectrum-analysis, it could be dispensed with altogether.

Striæ, as observed by the eye, have been divided into two classes, viz., the flake-like, and the flocculent or cloudy. Of the former, those produced in hydrogen tubes may be taken as a type; of the latter, those produced in carbonic tubes. But upon examining some tubes especially selected for the purpose, it was found that, while to this apparent a real difference corresponds, a fundamental feature of the striæ, underlying both, was brought out.

The feature in question was this: that the striæ, at whatever points produced, always have during the period of their existence a motion along the tube in a direction from the negative towards the positive terminal. This motion, which I have called for convenience the proper motion of the striæ, is for given circumstances of tube and current generally uniform; and its variations in velocity are at all times confined within very narrow limits. The proper motion in this sense appertains, strictly speaking, to the flake-like striæ only. The apparent proper motion of the flocculent striæ is, on the contrary, variable not only in velocity, but also in direction; and on further examination it turns out that the flocculent striæ are themselves compounded of the flake-like, which latter I have on that account called elementary striæ.

Elementary striæ are in general produced at regular intervals along the tube. The series extends from the positive terminal in the direction of the negative to a distance depending upon the actual circumstances of the tube and current. The length of

the column, and consequently the number of the striæ, depends mainly upon the resistance of the tube, the duration of the entire current, and to a certain extent upon the amount of the battery surface exposed, and in that sense upon the strength of the current. The velocity of the proper motion, other circumstances being the same, depends upon the number of cells employed.

The paper next gave descriptions of the phenomena exhibited by several tubes; and drawings illustrative of the descriptions were added.

The following are some of the general conclusions to which the experiments detailed in the paper seem to lead:—

1. The thin flake-like striæ, when sharp and distinct in their appearance, either are short-lived or have very slow proper motion, or both.

2 The apparent irregularity in the distribution of such striæ during even a single discharge of the coil, is due, not to any actual irregularity in their arrangement, but to their unequal duration, and to the various periods at which they are renewed. The striæ are, in fact, arranged at regular intervals throughout the entire column. The fluttering appearance usually noticeable is occasioned by slight variations in position of the elementary striæ at successive discharges of the coil. With a view to divesting the coil discharge of this irregular character, as well as for other purposes, I devised two different forms of contact breakers (one of which is described in the Royal Society's *Proceedings*, 1874); but I postpone a description of the second, as well as of the experiments arising from its use, to another occasion.

3. The proper motion of the elementary striæ is that which appertains to them during a single discharge of the coil. This is always directed from the positive towards the negative terminal. Its velocity varies generally within very narrow limits. It is greater the greater the number of coils employed. In some tubes it may be seen to diminish towards the close of the discharge, and even in rare instances alternately to increase and to diminish during a single discharge.

4. Flocculent striæ, such as are usually seen in carbonic acid tubes, are a compound phenomenon. They are due to a succession of short-lived elementary striæ, which are regularly renewed. The positions at which they are renewed determine the apparent proper motion of the elementary striæ. If they are constantly renewed at the same positions in the tube, the flocculent striæ will appear to have no proper motion, and to remain steady. If they are renewed at positions nearer and nearer to the positive terminal, the proper motion will be the same as that of the elementary striæ; if they are renewed at positions further and further from the positive terminal, the proper motion will be reversed.

5. The velocity of proper motion varies, other circumstances being the same, with the diameter of the tube. This was notably exemplified in the conical tube. In tubes constructed for spectrum analysis the capillary part shows very slight, while the more open parts often show considerable proper motion.

6. Speaking generally, the discharge lasts longer in narrow than in wide tubes. In spectrum tubes the capillary part gives in the mirror an image extending far beyond that due to the wider parts.

7. The coil discharge appears, in the earlier part of its development at least, to be subject to great fluctuations in extent. In all cases there is a strong outburst at first. This, although sometimes appearing as a bright line, is always, I believe, really stratified. Immediately after this there follows a very rapid shortening of the column. The extent of this shortening varies with circumstances; but when, as is often the case, it reaches far down towards the positive terminal, a corresponding diminution of intensity is perceptible in the negative glow. The column of striæ, after rising again, is often subject to similar fluctuations. These, which are sometimes four or five in number, are successively of less and less extent, and reach only a short distance down the column or striæ. The rifts due to these fluctuations then disappear, and the striæ either continue without interruption, or follow broken at irregular intervals, until the close of the discharge.

8. The effect of the proper motion, taken by itself, is to shorten the column of striæ. But, as we have seen, the striæ are in many cases renewed from time to time. In regard to this point, the head of the column presents the most instructive features. After the cessation of these rifts, the general appearance of the field is that of a series of diagonal lines commencing at successive points which form the bounding limit of the column at successive instants of time. If the points are situated in a horizontal line, the striæ are renewed at regular intervals at the same place; and the length of the column is maintained by a periodic renewal of striæ, a new one appearing at the head of the column as soon as its predecessor has passed over one dark interval. If the boundary of the illuminated field rises, the length of the column increases; if it descends, the column shortens. In every case, however, the growth of the column takes place by regular and successive steps, and not irregularly. The intervals of the new striæ from one another and from the old ones are the same as those of the old ones from one another.

9. The principal influence of a change in the number of cells used appears to consist in altering the velocity of proper motion. A change in the amount of battery-surface exposed produces a corresponding change in the duration of the entire discharge, as well as apparently in the development of some of the minor details of the striæ.

10. When the proper motion of the elementary striæ exceeds a certain amount, the striæ appear to the eye to be blended into one solid column of light, and all trace of stratification is lost. When this is the case the mirror will often disentangle the individual striæ. But there are, as might well be expected, cases in which even the mirror is of no avail, but in which we may still suppose that stratification exists. A variety of experiments have led me to think that the separation of the discharge into two parts, viz., the column of light extending from the positive terminal, and the glow around the negative, with a dark space intervening, may be a test of stratified discharge; but I cannot affirm anything certainly on this point.

Chemical Society, May 18.—Prof. Abel, F.R.S., president, in the chair.—The first paper read was on the action of malt extract on starch, by Mr. C. O'Sullivan, showing that under these circumstances it is converted into a mixture of maltose and dextrin, the proportion of which varies with the temperature at which the reaction takes place.—A communication was then made by Dr. H. E. Armstrong and Mr. Gaskell on metaxenol, the metadimethylated phenol.—There were also papers on the gases enclosed in cannel coals and in jet, by Mr. J. W. Thomas, on phenomena accompanying the electrolysis of water with oxidisable electrodes, by Dr. J. H. Gladstone and Mr. A. Tribe, and on the estimation of hydrogen occluded by copper, with special reference to organic analysis, by Dr. J. L. W. Thudichum and Dr. H. W. Hake.

Meteorological Society, May 17.—Mr. H. S. Eaton, president, in the chair.—James Lloyd Ashbury, John Broun, John Brown, Edmund Cruise, James Eldridge, George Garnett, John Hopkinson, Robert Pickwell, William Ford Stanley, Rupert Swindells, Charles Tarrant, Thomas Taylor Smith, were elected fellows of the Society. The following papers were read:—Remarks on the present condition of maritime meteorology, by Robert H. Scott, F.R.S. This paper gives a history of all that has been done in maritime meteorology since the Brussels conference in 1853, up to the present time.—In the mean temperature of every day at the Royal Observatory, Greenwich, from 1814 to 1873, by James Glaisher, F.R.S. This paper, which is a continuation of former ones on the same subject, contains the observations for the ten years, 1864 to 1873, which being combined with the previous ones, give the mean for sixty years. On the meteorology of Mozufferpore, Tinhoot, for 1875, by C. H. Pearson.—New wind chart, by Lieut.-Col. G. E. Bulger.

Physical Society, May 13.—Prof. G. C. Foster, president, in the chair.—The following candidates were elected members of the Society:—Prof. T. Andrews, Rev. R. H. M. Bosanquet, M.A., and David Howard.—Mr. Thompson, B.A., B.Sc., concluded the communication on the supposed new force, which he commenced at the last meeting of the Society. In the arrangement which he has adopted for obtaining the spark, the secondary current of a Rhumkorff's coil is made to traverse a short coil of wire which is thoroughly insulated from the internal core, and into the circuit an arrangement is introduced by means of which the current may be made to traverse a variable thickness of air in its course round the short coil. It is found that if this spark is very short the spark obtained from the internal core is also short, but as we increase the thickness of air to be traversed, the spark which may be drawn off increases; the greatest effect, however, is produced when one terminal of the coil is connected with the earth, the spark then obtained being about half an inch in diameter. Mr. Edison considered that the spark was retro-active, but Mr. Thompson showed, by an experiment,

that deficient insulation might lead to such a conclusion. He then proceeded to show that just as the charge given to a gold-leaf electroscope is at times positive and at times negative without any apparent reason for the change, so if the core of the arrangement employed be connected with a Thomson's galvanometer, the needle will be found to wander irregularly about the scale on both sides of the zero. In order to show that these experiments are identical with those conducted as originally described by the discoverer, the terminals of the induction coil were connected with the coil of an electro-magnet, the same means of including a layer of air in the circuit being introduced. The effect in this case was found to be precisely similar to that obtained with the special arrangement previously used; with a brush discharge a Geissler's tube could be illuminated, and, when the layer of air was infinitesimal, the spark produced was also infinitesimal. It was then shown that, if the spark at the point of contact in the key when a direct battery current traverses the coil be done away with by shunting the extra current which gives rise to it, no spark can be obtained from the core. It thus appears that no spark is obtained when there is no necessity for an inducing current to accumulate until it has sufficient tension to leap over a resisting medium, and that, as the thickness of this resisting medium increases, the spark obtained becomes greater. Evidently on these occasions the current has time to attract unlike and repel like electricity in the core, and if a conductor in connection with the earth be presented to this core, the like electricity will escape; hence a spark will result. As soon, however, as the tension has become sufficient to leap over the layer of air, it will be necessary to restore equilibrium in the core. Hence there will be a return spark in the opposite direction. From these experiments it will be seen that the phenomena observed may be explained by the ordinary laws of induction.

Institution of Civil Engineers, May 23.—Mr. Abernethy, vice-president, in the chair.—The paper read was on the permanent way of railways, by Mr. R. Price Williams.

CAMBRIDGE

Philosophical Society, May 8.—Mr. W. M. Hicks drew attention to some experiments of Messrs. Stewart and Tait on the heating of discs by rapid rotation in vacuo, and which they referred to the friction of the ether. It was shown that it was not necessary to have recourse to this explanation; that nearly all the effects could be accounted for if it is supposed that the disc, through the rapid rotation, has expanded and consequently been lowered in temperature; that whilst rotating it is raised to the temperature of the surrounding region; and therefore when the rotation is stopped, and the disc has shrunk to its former size, it will give out the heat it had taken in whilst rotating. In the case of silver it was shown that the disc ought to show a rise of ·4° C. if the rotation had been continued for some time, and this was compared with the rise of ·47° C. which Messrs Stewart and Tait had observed in an aluminium disc, thus showing that the effect was of the same order of magnitude in the two cases. It was also shown that if the whole heating were due to ethereal friction, that this friction would be ·0006 lbs. per square foot, and that if we suppose this amount to act on the surface of the earth, the day would be lengthened in the course of a century by something like ·006".—Prof. Maxwell afterwards made a communication on the equilibrium of heterogeneous substances.

STOCKHOLM

Royal Academy of Sciences, Feb. 9.—Herr Gyldén communicated a transformation of the formula—

$$\left\{1 + 2l_1 \operatorname{Cos}\left[2\, am \frac{2K}{\pi} + \Lambda\right] + l_1^2\right\}^{-\frac{n}{2}}$$

which plays an important *rôle* in the method of deducing a general formula of perturbation for periodic comets worked out by him. This transformation is mainly grounded on the relation—

$$e^{\sqrt{-1}\, am \frac{2K}{\pi}} = e^{\sqrt{-1}\, x} \frac{\eta(-x)}{\eta(x)},$$

where

$$\eta(x) = \left(1 - q e^{2\sqrt{-1}x}\right)\left(1 - q^3 e^{-2\sqrt{-1}x}\right)\left(1 - q^5 e^{2\sqrt{-1}x}\right)$$

and upon certain algebraic relations between different η-functions.

The final result is specially applicable when a comet comes to that part of its path which lies nearest the perturbing planets; in this case l becomes inconsiderably less than 1, and Λ may be taken to fall within exceedingly narrow limits in the neighbourhood of 0. The following papers were given in:—Myriopoda from Siberia and Waigat's Island, collected during Nordenskjold's expedition, 1875, by Anton Stuxberg. Eighteen species are described, of which only one was previously known to exist in Siberia, and fifteen are new to science, viz.—Lithobius 10, Iulus 1, Polydesmus 2, and Craspedosoma 2. Of the twenty-seven Siberian species now known only two are European.—Determinations of geographical position during the Swedish expedition to Novaya Zemlya and the Kara Sea, 1875, calculated by E. Jaderin.—On monœcism in fishes, by A. W. Malm.—Prof. Borenius communicated magnetic observations made at Helsingfors simultaneously with those made by the Swedish expedition at Spitzbergen during the winter 1872–3.

BERLIN

German Chemical Society, May 8.—A. W. Hofmann, president, in the chair.—E. Schunck and H. Römer by fusing Anthraflavinic and isoanthraflavinic acids with potash, have obtained two isomeric purpurines $C_{14}H_8O_5$. Anthrapurpurine is identical with a substance formerly obtained by Mr. Perkins; flavopurpurine obtained from the second of the two substances is the fourth isomeric purpurine.—A. Boettinger in studying anew the decomposition of tartaric acid by heat, believes that the formation of pyruvic acid is preceded by that of glyceric acid.—Dr. T. Stenhouse and C. E. Groves in treating pure naphthaline with sulphuric acid, obtained not only β-naphthaline-sulphurous acid, but also two napthaline-sulphones $C_{20}H_{14}So_2$, easily separated by sulphuret of carbon. They yield by oxidation two isomeric naphthaline-sulphuric acids.—T. Annaheim described dibromonitrooxysulphobenzid $(C_6H_2BrNO_2OH)_2SO_2$ and the corresponding iodo-compound. The same chemist described a red colouring substance obtained by the action of fuming sulphuric acid on cresol.—W. Rimarenko described β-chloronaphthaline obtained from β-naphthol and from β naphthaline-sulphuric acid with PCl_5,—the method formerly described by M. Clare.—E. v. Gorup Besancy and H. Will have investigated the liquid secretion of insectivorous plants (Nepenthes phyllaniphera). Albumine, fibrine, &c., are transformed into peptone. This digestion takes place in a very short time, when the secreting organ of nepenthes has been excited by contact,—the liquid having under these circumstances an acid reaction. The secretion of non-excited glands is rendered equally active by the addition of any acid, particularly of malic and citric acids.—H. Vogel published researches on the influence of different rays of light on bromide' of silver.—F. Tiemann and N. Matsnold have prepared nitro-protocatechic acid and some of its derivatives, also nitro-vanillinic acid and acetyl-nitro-vanillinic acid.—F. Tiemann and C. Reimer have obtained paraoxybenzoic aldehyde by treating phenate of potassium with chloroform.—E. Hoffmann described derivatives of hesperidine, particularly an acid $C_{10}H_{10}O_4$, which with potash yield protocatechic acid.

BRITISH MANUFACTURING INDUSTRIES

British Manufacturing Industries. By Various Authors. Edited by G. Phillips Bevan. (London: Edward Stanford.)

IN this series we have presented to us an account of the origin and development of those industries which have given this country her pre-eminence among nations. As stated by the editor, the object of the various treatises is simple and unambitious; no attempt is made to render them technical guides to the industries to which they relate; the main idea is to give, in as readable a form as is compatible with accuracy and a freedom from superficiality, the main features and present position of the leading industries of the kingdom, so as to enable general readers to comprehend the enormous growth of the last quarter of a century. The editor has been singularly fortunate in the selection of his co-operators. For example, Prof. Warington Smyth tells us all about the mines and collieries of the country; Prof. Hull discourses on quarries and building stones; Capt Bedford Pim on shipbuilding; Mr. Mattieu Williams finds congenial themes in iron and steel, gunpowder and explosives. The article on cotton by Mr. Isaac Watts, the Secretary of the Cotton Supply Association, is remarkably full and complete; Mr. Felkin's little treatise on hosiery and lace is a perfect mine of information, and forms a most interesting record of perseverance and effective skill; the stories of Jedediah Strutt and John Heathcoat will ever be two of the most thrilling chapters in the history of the industrial progress of this country. Indeed this series might have been fitly called the Romance of British Industry. We are told of Lee and the stocking-frame; of Wedgwood and Herbert Minton; of Hargreaves, Arkwright, and Crompton; of Dud Dudley and poor Cort; and of numbers of others, whose peaceful victories have done more for this country than all the machinations of her statesmen or the valour of her armies. *Apropos* of the invention of the stocking-frame it may be remarked that Elmore's well-known picture, representing Lee, after his expulsion from his college, intently watching the lissom fingers of his wife as she knits for the support of the household, in order that he might imitate their motion, is founded on a myth. Lee was a decent country curate in easy circumstances; he was never married, nor was he expelled from his college. But little is known of his history, beyond that, becoming greatly discouraged with the reception of his invention in this country, he passed over to France, where he died, neglected and in misery, in 1610. The history of the improvement of the stocking-frame is not less interesting than that of its origin. Since the time of Strutt, nearly 300 changes and adaptations have been patented, the vast majority of which are due to men who commenced life at the forge or bench, or at the frame itself.

The history of the rise and development of the lace manufacture is scarcely less remarkable, and Mr. Felkin has much to say concerning the personal history of its founders and of the trials and struggles of the inventors and improvers of lace-making machinery. Few trades have probably given rise to such an amount of litigation: indeed one can have no real conception of the immensity of the barrister's theme, or how eloquent he must have seemed to the beaver when—

> "he proceeded to cite
> A number of cases where the making of laces
> Had proved an infringement of right."

until he has read this essay. The story is painfully sad, and its moral is not lost on Mr. Felkin. "We cannot but remark," he says, "the extraordinary amount of latent inventive skill brought into operation by men entirely uninstructed in the science of mechanics; and be struck with the time and thought that the knowledge of sound mechanical principles would have saved them. . . . It is painful to notice how many of these men, possessing fine natural talents, from the want of self-government failed to use aright even the measure of profit that reached them. . . . Genius was to them rather a curse than a blessing. Here are strong arguments for higher scientific and moral education to be placed within reach of these classes."

Mr. Mattieu Williams concludes his capital little treatise on steel with a similar reflection. He indignantly protests against the fallacy of attributing our industrial success to coal or iron-stone, or to any other mere mineralogical or geographical accident. "It is not British minerals, but British industrial energy which has given us our industrial supremacy. It is not true that we are so exceptionally rich in coal. Many other nations possess vastly greater stores than ours; but while theirs has lain buried under their feet, ours has been brought to the surface and wonderfully used; to such an extent indeed, that we are actually approaching the limits of our supply before other and older people have tapped theirs. . . The same energies which have thus seized upon and utilised the rudest source of power to supply the coarser wants of ourselves and the rest of mankind, will if properly directed, similarly turn to account the more refined and recondite energies of nature which science is revealing, and which will supply in like manner the higher wants of more advanced civilisation. To succeed in this we must prepare at once, by affording to all classes the largest attainable amount of knowledge of the raw materials and powers of nature; of human means of turning these to profitable account; of the social organisation in the midst of which we live, and by which we are to co-operate industrially with each other and all the peoples of the earth; and above all, of the individual moral qualities, habits, and attainments that are necessary for each man's industrial success."

It is because other nations are actually turning to account "the more refined and recondite energies of nature" that our industrial supremacy is threatened. In chemical manufacturing, for example, the pre-eminence of the alkali trade belongs to us, but, as Prof. Church tells us, German, Austrian, and French manufacturers are far ahead of us in the production of the finer and more delicate preparations of the chemist, and still continue to make remarkable progress. "If a rare and curious substance, discovered by a scientific chemist and made in his laboratory painfully grain by grain, be found useful in medicine or dyeing, or some other art, straightway the foreign manufacturing chemist makes it, not by the ounce or pound merely, but by the hundredweight or

even by the ton." Much of the crude material which yields these beautiful and costly products of the continental manufactories is exported from England to be worked up and reimported. The reason of this lies in the more intimate union of science and manufactures which prevails abroad. The chemical manufacturer on the continent finds it to his interest to attach a sound and properly-trained chemist to his works to improve the established methods of production and to seek to discover new processes.

With the space at our disposal it is impossible to do more than merely indicate the scope and character of this series of excellent treatises. There are one or two little matters which need revision, and which the editor will doubtless set right in future editions: for example, the combining proportion of tin is not usually stated as 58, nor that of zinc as 32·6. Perhaps the most serious drawback is the very sparing use of illustrations. When given they are generally very good; nothing could exceed the beauty and finish of the cuts accompanying Mr. Watts' article on cotton. We are sorry that the example thus set has not been more generally followed. T.

HUTTON'S "GEOLOGY OF OTAGO"

Report on the Geology and Gold-fields of Otago. By F. W. Hutton, F.G.S., Provincial Geologist, and G. H. F. Ulrich, F.G.S., &c. (Dunedin: Mills, Dick, and Co.; London: Sampson Low and Co., 1876.)

THE Southern Province of New Zealand is one of great interest from the variety of its physical features which faithfully indicate the wide range of geological formations of which it is built up. The snow-clad ridge of "The Southern Alps," with numerous pointed peaks and serrated ridges, runs along the western coast, and is penetrated by deep "sounds," or fiords, not unlike some of those on the west coast of Norway. Mount Aspiring, at the northern border of the province, reaches an elevation of 9,940 feet, while several other points rise upwards of 8,000 feet above the sea, forming altogether a grand background, from which the rest of the country descends towards the eastern coast in a series of rolling downs, diversified by deep valleys and numerous lakes. The rivers are remarkable for, in several cases, and with much perversity, cutting through ridges, and crossing the boundaries of the formations, in a way that not long ago would have been attributed to the effects of mighty "convulsions of Nature," but which the physical geologist is now able to account for on very different principles. The Southern Alps contain glaciers which, as Mr. Hutton shows very clearly, extended considerably beyond their present bounds on two occasions in later Tertiary times, and to this agency he refers the excavation of the rock basins which now constitute nearly all the lakes of the hilly districts. An excellent view of this chain of snowy mountains will be found in Dr. von Hochstetter's elaborate work on New Zealand; in which Mount Cook, Mount Tasman, and the adjacent mountain giants are seen towering to an elevation of 13,200 feet above the waters of the ocean.

The work before us is a very carefully prepared, and scrupulously accurate, report on the physical features and geological structure of the district of Otago which, under the direction of Dr. Hector, the author has explored and mapped. The arrangement of the matter is good, and the descriptions succinct, while the writer is careful to notice the labours of others in the same field of research. The roughness of some of the woodcut illustrations, which one cannot fail to notice, is perhaps inseparable from a work brought out in a young colony, and is not to be laid to the charge of the author.

As already observed, the geological formations of Otago have a wide range in time, extending from the crystalline masses of the New Zealand Alps (possibly referable to the Laurentian period) through the representatives of the Lower Silurian, Carboniferous, Triassic, Jurassic, Cretaceous, and Tertiary times down to the present day. The thickness of some of these older formations is doubtless very great, but the difficulty which the author feels in estimating the apparent thickness of some of these formations at the amount deduced from the dip of the beds may probably be overcome by supposing that the beds are folded over on themselves—a phenomenon of very common occurrence in such districts as that of the New Zealand Alps. The Otago formations have very properly received names derived from localities where they are well represented. The reference to the equivalent formations in Europe is given with some hesitation; nevertheless, it cannot be doubted that on the whole these determinations are substantially correct—even if we suppose a relative, rather than an absolute, synchronism owing to the vast intervening space between Europe and New Zealand; and for all purposes of comparison it is not of the slightest importance whether it is one or the other.

The great oscillations of level through which New Zealand has passed are well described and illustrated by Mr. Hutton under the head of "Historical Geology." These correspond to some extent with the movements which in Britain and Europe have enabled us to define the limits of the three great divisions of geological time. Towards the close of the Palæozoic period "New Zealand probably formed a subordinate part of a large continent, which, judging by the similarity of the shells and plants, joined in the following formations with those of Australia, India, and Europe, probably stretched far away to the northward" (p. 75).

At the commencement of the Triassic period this continent began in New Zealand to be submerged; and with one or more slight oscillations this subsidence continued till towards the middle of the Jurassic period, when the whole country was again elevated, and the chain of the New Zealand Alps was formed. Great denudation of the upraised beds ensued, as they remained exposed to the atmosphere till the later Cretaceous period. Hence the unconformity between the Upper Cretaceous and the Lower Jurassic rocks (the Warpara and Putataka formations), and the entire absence of the intervening strata. Since the great upheaval here referred to, the New Zealand Alps have never been totally submerged, though sometimes deeply depressed.

The Upper Cretaceous period was one of submergence to all but the higher elevations, and at its close there was another elevation, accompanied by disturbances of the strata, resulting in an unconformity between the Tertiary beds and all those of older date. These former are found

filling in the depressions and old valleys of the Mesozoic and Palæozoic rocks, and often containing valuable beds of lignite resulting from the decay of the vegetation which found a congenial soil and climate amongst the lakes and lagoons of the period.

Mr. Hutton considers that there was a "Glacier period" during older Pliocene times, and another of less importance just before the Pleistocene epoch. Both of these are of earlier date than "The Glacial period" of the northern hemisphere, and in the view of the author, as well as of Dr. von Hochstetter and Dr. Haast,[1] were due not to climatical influences extending over the southern hemisphere and differing from those of the present day, but solely to the greater elevation of the land in New Zealand at those periods, and the consequent extension of snow and ice over a larger area than at present.

In Mr. Hutton, "The Theory of the Glacial Origin of Lakes," at least as far as it applies to the province of Otago, finds a new and welcome advocate; and his observations on this question are opportune at this time, as Prof. Ramsay's theory has been challenged by an able writer in the pages of the *Geological Magazine*.[2] Mr. Hutton first examines the views of those who have referred the origin of these lakes in Otago to subsidences, or terrestrial movements, and considering them inadequate, falls back on that of glacial erosion, in support of which he can appeal to the evidence of former glacial action along the shores of the lakes themselves.

The latter portion of the volume before us is taken up with the report of Mr. Ulrich upon the gold-fields of Otago, which is of much local interest, and will doubtless prove of value in guiding future adventurers, but does not appear to call for special observation in a short review.

OUR BOOK SHELF

Elementary Algebra, with Numerous Exercises, for Use in Higher and Middle-class Schools. By David Munn, F.R.S.E. (Collins' School Series, 1876.)

THE chief justification, perhaps, for the production of this work is that the exigencies of a "school series" demanded the publication of an elementary algebra. There is not much more in it than is to be found in a half-dozen similar works, and the explanations of rules seem to us to fall short of those given elsewhere. We do not like the frequent use of *evidently* in an elementary work; our own extended experience with English schoolboys is that these elementary details are by no means evident to the ordinary schoolboy mind. On p. 70 "the L.C.M. of a^3b^2c and $a^2b^3c^2$ will evidently be $a^3b^2c^3$" is evidently wrong, for it evidently ought to be $a^3b^3c^2$. Art. 8 on p. 45 (to show that when a certain algebraical polynomial is divided by $(x-a)$, the remainder is what the polynomial becomes when in it x is changed to a) is useful, and we teach it to advanced pupils, but we are disposed to think that few beginners could grasp the truth and apply it. On pp. 173 to 176 we have some interesting *Miscellaneous Propositions* on the progressions which we do not remember to have seen in previous textbooks. The most important mistakes we have found are on pp. 66, 96, 107, 151, 153. Here we may remark that there is a very plentiful crop of typographical blunders; many of these we are disposed to attribute to a hasty examination of the "proofs;" frequent instances, too, occur in which 2, 3, or 5 have got interchanged. There is a large collection of exercises, but happily no answers are given at the end, or the list of errata would doubtless have been greatly enlarged. From the fact that $(a^m)^n = (a^n)^m$ for positive integers, "it follows that $(a^{\frac{p}{q}})^q = a^p$." This, we think, will hardly be admitted; we should prefer to assume that the result holds, and thence derive an interpretation of $a^{\frac{p}{q}}$. The book takes in Indeterminate Equations, Permutations, Ratio, Proportion, Variation, and the Binomial Theorem. The only Scoticism we have noticed is one that frequently occurs: it is, "we will find," &c.

[1] See Hochstetter's "New Zealand," English translation, p. 504.
[2] No. 139, January 1867. The statements of Mr. Judd have called forth several rejoinders in the ensuing number of the *Magazine* for February.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

The Early History of Magnetism

PERMIT me to supplement "K.'s" excellent sketch of the "History of Magnetism" (NATURE, vol. xiii. p. 523) by two notices of the "Mariner's Compass," which seem to be of earlier date than any hitherto found in Europe. They possess particular interest from showing the compass in so rude a state as to lead to the inference that we owe it to a re-discovery rather than to an importation from China. The author of the notices is Alexander Neckam, an English writer of the twelfth century, and they are now included in a book which was privately printed in 1857, entitled "A Volume of Vocabularies," illustrating the condition and manners of our forefathers from the tenth to the fifteenth century, edited from MSS. in public and private collections, by Thomas Wright, M.A., F.S.A., Hon. M.R.S.L., &c. It was through the zeal and the liberality of Joseph Mayer, F.R.A.S., F.S.A., of Bebington, that these notices were brought to light, and a most useful volume was produced, of which he bore the charge.

As the discovery was made by Mr. Wright, it shall be reported in his own words. In referring to the many points of interest upon which new light is thrown by the vocabularies, he says:—

"None of these, perhaps, is of more importance than the curious early allusion to the use of the mariner's compass by the navigators of the western seas. It is well known to all readers that this invaluable invention has been formerly supposed to have been brought from the East, and not to have been known in the West until the fourteenth century, when it was used by the Italian mariners. Allusions to it have, however, been discovered by the students of mediæval literature in works which date as far back as the thirteenth century. In the following pages we find this invention not only alluded to in the twelfth century, but described in such a manner as to show that it was then absolutely in its infancy, and to leave little doubt of its having originated in the West. Alexander Neckam, in his treatise 'De Utensilibus,' enumerates among the ship's stores a needle which was placed on a pivot, and when turned round and left to take its own position in repose, taught the sailors their way when the polar star was concealed from them by clouds or tempest. I have discovered and printed in the note to this passage, a passage in another of Neckam's works, the inedited treatise 'De Naturis Rerum,' which gives a more distinct account of this invention. 'Mariners at sea,' he says, 'when through cloudy weather in the day which hides the sun, or through the darkness of the night, they lose the knowledge of the quarter of the world to which they are sailing, touch a needle with the magnet, which will turn round till, on its motion ceasing, its point will be directed towards the north.' A comparison of these two passages seems to show pretty clearly that at this time the navigators had no regular box for the compass, but that they merely carried with them a needle which had been touched with the magnet (perhaps sometimes they carried the magnet also, and touched the needle for the occasion), and that when they had to use it they merely placed it upon some point, or pivot, on which it could turn with tolerable freedom, and then gave it a motion, and waited until it ceased moving. This mode of

using the needle was, it must be confessed, rude enough. The passage in the treatise 'De Utensilibus' contains one particular which is very obscure, as Neckam informs us that when the needle ceased moving it pointed towards the east (*donec cuspis acus respiciat orientem*), and as all the manuscripts agree in this reading, and it is glossed by *est*, this must be the intention of the writer I know no way of explaining this, unless it be by the supposition that as in the twelfth century, the East was the grand object of most voyages from this part of the world, an attempt had been made to improve the magnetic needle, by adding to it a limb at right angles, which should point to the east when the needle itself pointed to the north, and that this was what Neckam called the *cuspis acus* Between this and the date—whatever it may be—of the poem, also quoted in my note on the passage of Neckam, which contains the first allusion to the mariner's compass in the thirteenth century, an attempt had been made to facilitate its use [1] This was done by thrusting the needle through some substance which would not sink, and placing it upon the surface of water Guiot de Provins, the author of the poem alluded to, calls this substance a *festu*, a stick or straw (the Latin *festuca*) The mariners, he tells us, have a contrivance depending on the magnet, which cannot fail The magnet, he adds, is an ugly brownish stone, to which iron is attracted 'After they have caused a needle to touch it, and placed it in a stick, they put it in the water, without anything more, and the stick keeps it on the surface Then it turns its point towards the star with such certainty that no man will ever have any doubt of it, nor will it ever for anything go false When the sea is dark and hazy, that they can neither see star nor moon, they place a light by the needle, and then they have no fear of going wrong, towards the star goes the point, whereby the mariners have the knowledge to keep the right way It is an art which cannot fail' According to another poet, the substance through which the needle was usually thrust was cork He tells us that 'the mariners who went to Friesland, or to Greece, or Acre, or Venice' were guided by the polar star, but when at night, or in obscure weather, it was invisible, they discovered its position by the following contrivance - 'They thrust a needle of iron through a piece of cork, so that it is almost buried in it, and then touch it with the loadstone, then they place it in a vessel full of water, so that no one pushes it out until the water is calm, for in whatever direction the point aims, there without doubt is the polar star' The MS in which this latter poem was found is undoubtedly of the fourteenth century, but the poem itself is evidently of somewhat older date of the beginning of that century, or not improbably of the century preceding It is possible therefore that this rudely constructed mariner's compass may have continued unimproved until the fourteenth century" [2] (*Introduction*, pp 16 18)

[1] In this interval we meet with another slight but very curious allusion to the use of the magnetic needle for the purposes of navigation Jacques de Vitri, one of the historians of the Crusades who wrote about the year 1 18 says ("Hist Hieros, cap 89) — Acus ferrea, postquam adamantem contigerit, ad stellam septentrionalem, quæ velut axis firmamenti aliis vergentibus non movetur, semper convertitur unde valde necessarius est navigantibus in mari'

[2] This very curious poem, a sort of song, is preserved in a manuscript formerly in the collection of M Barrois of Paris, and now in that of Lord Ashburnham It was first pointed out by M Fr Michel, who printed the portion relating to the mariner's compass in the preface to his 'Lais Inedits (Paris, 1836) As this is now a rare book, I have thought it desirable to give here the whole passage as a complement to the extracts given in the note on p 114 of the present volume It is as follows —

"I a tresmontaigne est de tel guise
Qu'ele est el firmament assise
Ou ele luist et reflambie
Li maroniers qui vont en Frise,
En Grese en Acre ou en Venisse,
Sevent par li toute la voie
Pour nule riens ... se de voie,
Tout jours se tient en une more
Tant est de li grans li servisse,
Se la mers est enflee ou koie
Jà ne sera c on ne le voie,
Ne pour galerne ne pour bise

Pour bise, ne pour autre afaire
Ne laist sen dout servise à faire
La tresmontaigne clere et pure,
Les maroniers par son esclaire
Jete souvent hors de contraire,
Et de chemin les asseure
Et quant la nuis est trop oscure,
S est ele encor de tel nature,
Qu al aimant fait le fer traire,
Si que par forche et par droiture
Et par ruille qui tous jours dure,
Sevent le liu de son repaire,
Son repaire sevent a route,
Quant la nuis n a de clarte goute,
Tout chil qui font cest maistrise,
Qui une aguille de fer boute
Si qu ele pert presque toute
En i poi de liege et l atise
A la pierre d aimant bise
En i vais el plain d yave est mise,
Si que nus hors ne la deboute,
Si tost com l iave s iserise,
Car dons quel part la pointe vise,
La tresmontaigne est la sans doute"

The following is the text of Neckam with the interlinear gloss:—

ille une pere faut naute
"Qui ergo vult habere navem, albestum habeat, ne desit ei
fu aguyl mis
beneficium ignis [1] Habeat etiam acum [2] jaculo suppositam,
turne e enurun aguyl poynt agardet
rotabitur enim et circumvolvetur acus donec cuspis acus respiciat
est tal modo i ubi mariners
orientem, sic que comprehendunt quo tendere debeant naute cum
cinossura" [the cynosure, κυνόσουρα, or constellation popularly
atapist de leyr tempeste cinossura
called Charles's wain] "latet in aeris turbacione, quamvis ad
achecement circle petit
occasum nunquam tendat propter circuli brevitatem." ("De Utensilibus," p 114)

Mr Wright adds "The earliest account of the mariner's compass, before known, was contained in the following lines of a satirical poem, entitled the 'Bible Guiot de Provins,' composed in the thirteenth century (Barbazan, "Fabliaux," tom ii p 328)

" Un art font qui mentir ne puet
Par la vertu de la maniete,
Une pierre laide et brunete,
Ou li fers volontiers se joint
Ont si esgardent li droit point
Puis c une aguile i ont touchie,
Et en un festu l ont couch
En l eve le metent sanz plus
Et li festuz la tient desus
Puis se torne la pointe toute
Contre l estoile si sanz doute,
Que jà nus hom n en doutera,
Ne jà por rien ne fausera
Quant la mers est obscure et brune,
C on ne voit estoile ne lune,
Dont font a l aguille alumer,
Puis n ont il garde d esgarer
Contre l estoile va la point
... ont li mariner cointe
De la droite voie tenir
C est uns ars qui ne puet faillir

The language of the last extract fully bears out Mr Wright's estimate of it as not earlier than the thirteenth century

WM CHAPPELL

The Dry River beds of the Riviera

MR H T. WHARTON's letter (NATURE, vol xiii, p 448) does not seem fully to explain the difficulty expressed by Mr R. I Bartlett (NATURE, vol xiii, p 406), a difficulty which is often felt by many of the visitors to the Riviera Mr Wharton is quite correct with regard to the Paglione This stream has, I believe, within the last few years been often in high flood, and has been more than once within a foot or two of the top of the arches of the bridge which Mr. Bartlett seems to think is unnecessarily large The Paglione, where it passes through Nice, is not, however, a fair representative of the river-beds of the Riviera. When the river walls were built, which now retain the Paglione, the river bed was, in all probability, made much narrower than it previously was, on account of the value of the land for building purposes, and only so much of the river-bed retained as was necessary to carry away the water, so that the Paglione now completely fills its channel when in flood This is far from

[1] It was believed that the asbestus, when once lighted, could never be extinguished, and hence Neckam recommends it to be carried on shipboard, that the sailors may never be without fire

[2] This rather obscure description of the mariner's compass, belonging certainly to the twelfth century, is the earliest allusion to the use of that important instrument in the middle ages Alexander Neckam has, however, given a rather fuller description of it in another of his books, the treatise "De Naturis Rerum, lib 2, c 89 (MS Reg. 12 G xi, fol 53 v°). "Nautæ etiam mare legentes, cum beneficium claritatis solis in tempore nubilo non sentiunt, aut etiam cum caligine nocturnarum tenebrarum mundus obvolvitur, et ignorant in quem mundi cardinem prora tendat, acum super magnetem ponunt, quæ circulariter circumvolvitur usque dum, ejus motu cessante, cuspis ipsius septentrionalem respiciat." [Here the error about pointing to the east is corrected]

being the case with most of the Riviera torrents. For instance, the channels of the streams near Menton, Vintimiglia, and elsewhere, are far out of all proportion to the work they have to do. Take the case of the principal stream at Menton. At a distance of less than two miles from the sea where its bed is formed of rock, it has only a breadth of a few yards, and has no high flood-marks indicating that there is ever a great depth of water. If the stream is followed downwards from this point for less than a mile, the bed is found to open out to a breadth of from sixty to seventy yards. Between these points there are no tributary streams adding their waters to account for this increase. These large river-beds are caused by the nature of the country which these rivers drain. The country is very mountainous, the hill slopes are rocky and steep, large areas have no covering of soil, and what soil there is does not retain the water well. The result of this is, that when rain falls the water rapidly finds its way to the streams, and the same amount of rainfall is discharged by these streams in a few hours as is discharged in weeks by an English river draining the same area. This accounts for these torrents rising so "high" and falling so "low." It also accounts for them "rising" and "falling" rapidly.

But further, the great and unnecessary breadth of these torrent-beds where they approach the sea seems to be produced somewhat in the following way:—The valleys through which these streams flow descend rapidly from the mountains, but as they approach the sea their slope becomes much slower; the result of this is, that the gravel brought down by the river from its higher and more rapid reaches, is here deposited, on account of the water losing its velocity, and the bottom of the valley becomes filled with a bed of gravel, through which the stream winds sometimes in one part, sometimes in another. A very small cause being sufficient to make the stream "cut" into the gravel and alter the position of its bed, and cause it to flow in different parts of the channel at different times, but it almost never covers at one time the whole breadth of it.

That the bed of the principal stream at Menton is unnecessarily large, is evident from the fact that now, on account of the increased value of land, they are building a retaining-wall near the centre of the stream, and filling up about one-half of the river-bed for the purpose of cultivation.

Rivers similar to those of the Riviera are common to all mountainous countries, Britain not excepted. There is at least one salmon river in Scotland, which during the dry season may be walked across without wetting the soles of one's boots, all the water finding a passage among the gravel. Yet in Autumn, when it has fallen to "fishing condition," it is a stream of about thirty yards broad, and an average depth of about two feet on the fords. This river is also subject to great floods, which "come down" rapidly, and "fall" rapidly. It also has gravel deposits similar to those of the Riviera torrents, but in this case they are covered with soil and cultivated, and it is with the greatest difficulty and at great expense that the river is prevented from widening its channel to the proportions of those of the Riviera torrents. Method of Distributing Astronomical Predictions

I BEG leave to observe that the very useful method of distributing astronomical predictions over a given geographical area alluded to in NATURE, vol. xiii., page 71, and ascribed there to Mr. W. S. B. Woolhouse, was already proposed by my father, J. J. von Littrow, in his treatise, "Darstellung der Sonnenfinsterniss vom 7 September; 1820," Pest, 1820, as well as in the *Berliner Astronomisches Jahrbuch*, for 1821, page 116, and 1822, page 145; subsequently in his "Theoretische und practische Astronomie," Wien, 1821, part ii., page 280; and last in his "Vorlesungen über Astronomie," Wien, 1830, part i., page 306. Since then numerous applications have been made thereof. My father expressed the well-founded desire that in the astronomical almanacs formulæ might be given similar to that communicated in NATURE. CHARLES DE LITTROW

Acoustical Phenomena

IN connection with Doppler's disputed theory of the colours of stars, the illustration usually employed to assist the mind in forming a conception of the hypothesis is that of the whistle of a passing locomotive. The note of the whistle, which, as it approaches, seems shriller than its normal pitch, owing to the greater number of vibrations impinging upon the ear in the unit of time, falls half a tone more or less, as the engine passes and recedes. To unmusical ears the difference in the note is a very doubtful fact, only to be taken on hearsay. There is, however, another fact of kindred nature to which attention has not, I believe, been generally drawn. Almost all railway engines, and especially those drawing heavy goods' trains, have, owing to the manner in which the valve-gearing is set, the property of producing the well-known *staccato* puffs of steam, audible to the ear as well as evident to the eye. Anyone who will listen to these puffs as the train dashes by will be aware of a very distinct and well-marked change in their apparent rapidity of succession at the moment of passing. So distinct is the change that almost invariably the first effect on the mind is the illusory suggestion that the train has suddenly slackened speed. This change is heard best at night, and when the passing train is a heavy one, not running too quickly. It cannot fail to be appreciated even by non-musical ears. As an illustration of a scientific principle it is, perhaps of the greater value, as a popular error seems to exist on the subject of the change of the note of the whistle, to the effect that the lowering in pitch is very gradual during the approach and recession of the engine, an opinion obviously incorrect if the observer be close to the train.

London, June 7 S. P. THOMPSON

Giant Tortoises

IN NATURE, vol. xiv. p. 60, it is stated that Commander Cookson, of H.M.S. *Petrel*, is bringing home two live specimens of the giant tortoise of the Galapagos; that *if* their food lasts, and *if* they are not killed by the cold off Cape Horn, they will be the first specimens seen alive in this country.

Even should the tortoises survive the two *ifs* above given, they will not be the first living specimens seen in this country.

A large specimen brought from the Galapagos Islands by one of the ships of the late S. R. Graves, M.P., lived in good health for nearly ten years in our Dublin Zoological Gardens.

This animal was examined, after death, by Dr. Gunther, who states that it is not identical with the Indian species, as supposed by former naturalists. SAMUEL HAUGHTON,
Secretary Royal Zoological Gardens, Dublin

Trinity College, Dublin, June 2

Photography of the Loan Collection Apparatus

THE Loan Collection of Scientific Apparatus at South Kensington contains many apparatus, as for instance the first air-pump of Otto von Guericke, the first boiler of Papin, the first locomotive, &c., which for the friends of science will ever be of great historical interest. Therefore I cannot refrain from expressing the wish that opportunity should be given to take photographs of convenient size of some of the most interesting apparatus. I believe many visitors will feel with me greatly gratified if such a more enduring remembrance could be taken home of an exhibition that perhaps for ever will remain unequalled.

The Hague, June 12 L. B.

ABSTRACT REPORT TO "NATURE" ON EXPERIMENTATION ON ANIMALS FOR THE ADVANCE OF PRACTICAL MEDICINE

THE courteous request of the editor of NATURE that I should contribute to his pages an abstract of my experience of the value of experimentation on animals and on the most useful applications of that method of research to the alleviation, directly or indirectly, of animal suffering in all the higher classes of animals is responded to in the subjoined notes.

I have already expressed my views on this subject on two occasions at large public meetings of the Royal Society for the Prevention of Cruelty to Animals, and in 1862 I made a report on the same subject to the indefatigable secretary of that society, Mr. Colam, which report he has recently published, and which on the points it refers to is in harmony with the conclusions of the late Royal Commission. I have not, however, entered into the discussion that for some months past has been in

progress, and this for the simple reason that in the violence, I had almost said distemper, of the controversy, I felt I could take no part. In what I am now about to record I shall merely bear witness of what I know without prejudice to either side. I state this at once because I feel morally sure that if I had not been a physician, and if I had not from that circumstance studied the question in connection with human suffering in its most poignant aspects, I should have been one of the strongest partizans amongst those who are most strongly opposed to experimentation. I differ indeed only from them in that I have been obliged to consider the pains of men, women, and children in my daily labours, and have been forced to the conviction that the actual suffering of the inferior animals bears no comparison with that which is borne by the human family; that the mental sufferings alone of man exceed the physical pains of the lower creatures; and that his physical pain is greater in amount, in intensity, and in appreciation.

For my part, the experience I have gained from experimentation has, from the beginning to the end, through a long period of twenty-six years—during which it has at intervals been sought—sprung in almost every instance, directly from the desire to apply scientific research to the instant use of the practising physician. With rare exceptions every inquiry has been prompted by some painful difficulty that has been suggested at the bedside of the sick, or by the sight of operation on the human subject.

If, therefore, experiment on animals can be vindicated by its application to practice, my experience may be of use in settling doubts in the minds, at least, of those who are not unduly biassed on either side.

Experimentation on Death from Chloroform

The first series of experiments I remember to have made were commenced in the years 1850 and 51, and had reference to the mode and cause of death under chloroform. At the time named chloroform had been in use a little over two years, for preventing the pain of surgical operations, and already nineteen deaths in man had occurred from it.

These calamities had produced very painful and anxious feelings amongst medical men, and my researches had for their intention the elucidation of many points of practical importance. The mode of procedure was to narcotise the animals with varying degrees of rapidity, with varying percentages of chloroform vapour in the atmosphere, and during various atmospherical conditions: to note carefully the phenomena produced on the heart and on the respiration, and the duration of the four stages of narcotism. In some instances the animals rabbits were usually subjected to experiment—were allowed to recover; in other instances the narcotism was continued to death. When the narcotism was made to be fatal the immediate cause of death was noted, and the body was left until the rigidity of death could be recorded. Then all the organs were carefully inspected in order to see what was the condition of the lungs, the heart, the brain, the spinal cord.

The results obtained by these inquiries were of direct practical value. By them I showed in various lectures and papers the following major facts:—

1. That the cause of the fatality from chloroform does not occur, as was at first supposed, from any particular mode of administration of the narcotic.

2. That chloroform will kill, in some instances, when the subject killed by it exhibits, previous to administration, no trace of disease or other sign by which the danger of death can be foretold.

3. That the condition of the air at the time of administration materially influences the action of the narcotic vapour. That the danger of administration is much less when the air is free of water vapour and the temperature is above 60° but below 70° Fahr.

4. That there are four distinct modes of death from chloroform, and that when the phenomena of death from its application appear, they are infinitely more likely to pass into irrevocable death than from some other narcotics that may be used in lieu of chloroform.

5. That all the members of the group of narcotic vapours of the chlorine series, of which chloroform is the most prominent as a narcotic, are dangerous narcotics, and that chloroform ought to be replaced by some other agent equally practical in use, and less fatal.

6. That so long as it continues to be used there will always be a certain distinct mortality arising from chloroform, and that no human skill in applying it can divest it of its dangers.

That knowledge of this kind respecting an agent which destroys one person out of every two thousand five hundred who inhale it was calculated to be useful no reasonable mind, I think, can doubt. To me who, many hundred times in my life have had the solemn responsibility of administering chloroform to my fellow-men, it was of so much value that I should have felt it a crime if I had gone blindly on using so potent an instrument without obtaining such knowledge.

Experimentation with reference to the Deposition of Fibrine in the Heart, and Prevention of Death from that Cause.

From 1851 to 1854 I was closely occupied in the study of that mode of death which is caused by the separation of the fibrine of the blood in the cavities of the heart. At the time named a medical controversy which had been all but silent for a hundred and fifty years, on the question whether the separations of fibrine which are often found in the heart after death are formed before death and are a cause of death, or are formed after death and are a mere consequence, was revived and was carried on, with much activity, by physicians of different schools. I took a leading part in supporting the view that the separations of fibrine took place, as a rule, before death, and were the cause of death. I did a great deal to prove the truth of this then controverted, and now universally admitted, position, and I gave the first detailed description of the symptoms which indicate the formation of the clots in the cavities of the heart. The result was that I soon became too sadly familiar with this class of case, for I found that the symptoms, whenever they were fairly pronounced, indicated the certain death of the sufferer. These observations led me, naturally, to look for a remedy; to an endeavour to find a means by which the clot of fibrine in the heart could be made to undergo solution. Taking clots that had been removed from the dead and had been causes of death, I subjected them to different solutions to determine their solubility. I found them soluble in some alkaline solutions, and amongst other solutions in ammonia. I also observed that ammonia added to blood held the fibrine of the blood, from which these clots are formed, in solution. The fact led me to expect that by the use of such alkaline solutions a true solvent remedy might be found. A case occurred in which symptoms of fatal character were fully developed, and in the hope of producing solution of the coagulum in the heart, full doses of bicarbonate of ammonia were repeatedly administered. To my great satisfaction the signs of oppression at the heart ceased, life was evidently prolonged, and a fair chance of recovery was presented. The hope of recovery was in a few hours, however, destroyed; coma supervened, and the patient died from that added cause of death. The *post-mortem* revealed that the blood throughout the body was fluid, and that the clot which had been in the heart had undergone all but complete solution. But the red corpuscles of the blood were found also to have undergone the extremest disintegration, and the brain and other vital organs were intensely congested.

The inference I drew at this time, it was in 1854, from

the example in question, was that the remedy which had caused solution of the coagulum had saved life by that process to destroy life by the extension of the solvent action to the blood corpuscles, and this opinion was so fully confirmed by experimentation, that I gave up further inquiry on the subject, from the feeling that its continuance was not warranted. A period of seventeen years now elapsed, in every year of which I had occasion to see from five to six instances of death from this one cause. Some of the deaths from the cause named occurred after surgical operations, such as ovariotomy, some from croup and other inflammatory affections, others before or after childbirth. In 1870 I computed that I had witnessed ninety-seven of these fatal catastrophes. Meantime there had been found no remedy, but I had learned from the added experience one new fact, viz., that in three instances, although no ammonia or other solvent of the blood had been employed in treatment, the symptoms of coma supervened precisely as in the case where ammonia had been administered. At last I obtained one clear evidence that the reason of the symptoms was a separation of fibrine in the sinuses of the brain.

Recurring once more to the use of ammonia as a solvent of the deposited fibrine, I thought it justifiable now to renew experiment. It might, I felt, be the best course to administer the simple liquid ammonia instead of a salt of that substance, by which means I hoped the solvent action would be obtained by an agent that was more easily eliminated from the body when the administration of it was withdrawn.

To what extent I might administer the solvent, how far I might venture to produce disintegration of the corpuscles of the blood and hope for recovery, was the point to be arrived at. It could only be arrived at by one of two methods—by trying the experiment on the inferior animals, or by waiting for the opportunity of testing the remedy directly on man in some extreme case of the diseased condition specified. I chose, and I think correctly, the first of these alternatives. I subjected an animal, a guinea pig, to the administration of ammonia diluted as it might be for the human subject, and I continued the administration until I found, firstly, that life was possible and safe under a degree of solution of blood which in the absence of such a direct test would have been thought impossible; and secondly, that on the withdrawal of the solvent agent the natural state was slowly but completely restored. I repeated the research in order to test the best mode of administration. I tried on myself the doses that could be swallowed without actual pain, and then I planned the measure I would adopt when another instance of obstruction of the blood in the heart came under my care. I need not repeat here, in any detail, the satisfactory results of this inquiry. The facts have been recorded at length before the Medical Society of London, have been made widely known in the profession of medicine, and have gathered confirmation from others. It is sufficient for me to state that in 1872, in an example of this fibrinous obstruction in the heart, when the sufferer was to all known observation *in extremis*, the treatment by ammonia, in doses which would have been considered poisonous had not experiment on animals proved the contrary, was pushed to the full; that the evidence of solution of the obstructing mass in the heart was perfect; and that complete recovery, I have no doubt the first recovery of the kind, was the result. Since then I know of eight more examples in which the same rational method of treatment has been applied, with the result of six recoveries.

Experimentation for Surgical Learning.—Ovariotomy.

I have sometimes had occasion to perform, or take part in experiments on the lower animals in order to learn some important detail of *surgical* practice. The following experience of this nature is worthy of special note.

When Mr. Spencer Wells was beginning his career in performing the operation of this century, —the removal of ovarian tumours,—a difficulty arose on the point whether in closing up the wound in the abdomen the peritoneum ought or ought not to be included in the stitches. At the present time, when so much is known, this subject may appear of little moment; then it was of vital moment. The peritoneum had been held by all authorities to be of such importance in the animal economy that to cut or injure it was thought to be actually a deadly act, and a man who intentionally injured the peritoneum, in operation, was considered, by many, as little better than a wanton and wicked experimenter on human life. Ought any one, therefore, to venture to put two rows of stitches through this structure? Mr. Wells wished to ask the question of nature, by experiment, and I helped him. Eighteen animals of three classes—guinea-pigs, rabbits, and dogs—were first thoroughly narcotised. Then the same incision was made into the abdominal cavity as is made in ovariotomy. Afterwards the incision was neatly and closely sewn up, in one set of experiments with the peritoneum included in the stitches, in the other set with the peritoneum excluded. The animals, on coming out of their sleep, were attended to and treated with as much care as if they had been human until their recovery, which in each case was rapid and easy. When they had entirely recovered and the wound healed, they were submitted to painless death, under anæsthesia, and their bodies were examined to determine the results of the different modes of operation.

These were the steps of the proceeding. The lessons taught were of vital value. The experimentation proved beyond dispute that the introduction of the stitches through the peritoneum added no danger to the operation. They proved further that when the peritoneum was included in the stitches, the wound healed much more firmly and safely, *a fact which could only have been learned from an operation on a subject that could be killed after operation.* From that time of probationary learning on to this time of matured experience, Mr. Wells has performed the great operation, with which his name is for ever identified, 770 times. In every instance the patients who have come under his care for operation would, presumably from past experience, have died from the disease. Of his patients operated on an average of three out of four have recovered. He has, therefore, by his own hand saved between five or six hundred women from one form of certain and lingering death. Towards this result—a result grander than has ever before fallen to the lot of any operator of any age he was fortified by the experiments I have described to an extent which no one but an operator himself can fully appreciate.

I am aware there are some who would urge that he might have learned the facts he wanted to obtain by experience, that is to say he might have waited for the results from his operations on women. This plan would have made several women in the prime of life subjects of experimental inquiry. I am aware that some would say it were better the operation had been dropped than that any animal whatever had been subjected to suffering for its sake. This plan would have been an obstacle to the saving of over five hundred women from early and certain death in the practice of Mr. Wells alone. But when it is remembered that his teaching and example have been followed wherever surgery is practised, the numbers of women saved from death and suffering during the last fifteen years in consequence of what was learnt by sacrificing some eighteen dogs, rabbits, and guinea-pigs, it is obvious that those who estimate human life at its real value and observe human suffering in its most distressing forms are compelled, however painful to their own feelings, to think and act first for the best interests of the human family.

What Lord Selborne, one of our most distinguished

Chancellors, thinks of the results of Mr. Wells's work may be gathered from one of his published speeches. He calls it "one of the most splendid triumphs of modern surgical art and modern philanthropy, one of the greatest achievements of medicine or surgery in any age." Mr. Wells himself has repeatedly urged that what he learnt by the result of the experiments we performed together has been of the utmost importance for the success of the operation, and in a note addressed to me to-day he repeats and permits me to publish his views in his own words :—

"The few experiments we made on the narcotised animals taught in a few weeks, in the early days of ovariotomy, what I could not have learned to this hour, after many years' observations on suffering women. To my mind, the loss to the world by the few animals sacrificed, when compared with the gain by the lives of the thousands of suffering women already saved, wherever the improved methods of operating learned by these experiments has been followed, is so utterly disproportionate as not even to be worthy of consideration."

BENJAMIN W. RICHARDSON

(*To be continued*)

OUR ASTRONOMICAL COLUMN

THE COMET OF 1698.—The orbit of the comet of 1698, which appears in our catalogues was calculated by Halley from the observations of Lahire and Cassini at Paris. In his "Synopsis of the Astronomy of Comets" he remarks that the comet "was seen only by the Parisian observers who determined its course in a very uncommon manner. This comet was a very obscure one, and although it moved swiftly, and came near enough to our earth, yet we, who are not wont to be incurious in these matters, saw nothing of it."

The comet was detected on Sept. 2, between β and κ Cassiopeæ, and thence pursued a southerly course until on the 28th of the same month it was last observed between ξ and ψ Scorpii. On calculating geocentric places from Halley's orbit, it appears that the elements as originally published by him, and as they have been successively copied into all our catalogues, give an apparent track in the heavens which is totally different from that recorded by Lahire and Cassini, and described in *Anciens Mémoires de l'Academie des Sciences*, t. x., and which is traced on the chart in the *Mémoires* for 1702. Employing positions deduced as closely as practicable from the somewhat imperfect details in our possession, for Sept. 2, 15, and 28, the following orbit results :—

Perihelion Passage 1698, Sept. 17·0214 Paris mean time.		
Longitude of the perihelion ...	274° 42′	Equinox
,, Ascending node ...	65 53	of 1699.
Inclination	10 55	
Log. Perihelion Distance ...	9·86252	
Heliocentric motion — retrograde.		

On comparing these elements (which very fairly represent the apparent track of the comet) with Halley's, it is at once evident that the cause of the failure of the latter is the substitution in the "Synopsis" of the longitude of the *descending*, instead of that of the *ascending* node, an oversight which appears to have escaped detection hitherto. Making this change in Halley's elements they will stand as follows :—

Perihelion Passage 1698 Oct. 18 at 16h. 57m. Greenwich		
Longitude of Perihelion ...	270° 51′ 15″	time.
,, Ascending Node	87 44 15	
Inclination	11 46 0	
Log. perihelion distance ...	9·83966	
Motion — retrograde.		

The first orbit appears to agree better upon the whole with the path of the comet laid down in the above mentioned diagram.

THE BINARY STAR ω LEONIS.—In the "Transactions of the Royal Irish Academy," vol. 26, Dr. Doberck has given the details of a very elaborate determination of the orbit of this star, on measures extending to the spring of the present year. Madler had previously given two orbits, Villarceau one, and Klinkerfues three, so that the object had not been neglected, but a longer course of measures than had been employed by these calculators was required for a trustworthy approximation to the orbit. Dr. Doberck presents the following elements as definitive for the present :—

Peri-astron passage	1841·81
Node	148° 46′
Angle between the lines of nodes and apsides (λ)	121° 4′
Inclination	64° 5′
Excentricity	0·5360
Semi-axis Major	0″·890
Period of revolution	110·82 years.

From these elements we deduce the following angles and distances, exhibiting the course of the companion during the present century :—

1878·0	Pos. 75°·1	Dist. 0″·56	1890·0	Pos. 102°·4	Dist. 0″·75
82·0	,, 86·0	,, 0·62	94·0	,, 108·5	,, 0·82
86·0	,, 95·0	,, 0·68	98·0	,, 113·6	,, 0·89

Some remarks on the correction of orbits of double stars, appended by Dr. Doberck to his paper on ω Leonis, one of the most complete of the series emanating from Col. Cooper's Observatory at Markree Castle, may be useful to those who are occupied with these orbits.

VARIABLE STARS.—(1) Olbers' supposed variable, near 53 Virginis. Mr. J. E. Gore, writing from Umballa, Punjab, on May 13, says he examined the place of this star a few nights previous with a 3-inch refractor, and found it about 9 m., being about equal in brightness to Olbers' star *c*, and brighter than his star *d*, which latter appeared more nearly 9½ or 10 than 11, as given by Olbers. With an opera-glass the suspected variable was "about the faintest star in the immediate vicinity of 53 Virginis."

(2) 5 Ceti.—Recent observations afford a suspicion of variability to a small extent in this decidedly reddish star, which, by the way, is not found in Schjellerup's second catalogue of objects of this class. It may be advantageously compared with its neighbours 4 Ceti and B.A.C. 5. (3) The Companion of Algol. The small star near β Persei, appears to have been first remarked by Schroter, on October 12, 1787, with a 7-feet telescope, power 160; on November 3 the distance was estimated 1′ 30″. On April 9, 1788, he could not find the small star, and hence concluded it to be variable. Observations during the last two or three years have rather indicated fluctuation of brightness, the star being sometimes caught at once, and at others only perceived with difficulty, employing the same telescopes and on nights not differing materially in transparency. It would not be without interest to ascertain definitely by systematic observation whether there is any ground for the suspicion first entertained by Schröter.

THE DOUBLE-STAR γ CENTAURI.—Will one of our southern readers put upon record the actual angle of position and distance of this object, to decide upon the direction and amount of the motion, which at present are by no means obvious? Capt. Jacobs' measures in December, 1857, showed that the star was widening, as compared with his estimate in March of the preceding year, but he found a retrograde change of angle to the amount of 7°, whereas the angle of 1856, compared with Sir John Herschel's measures in 1835-36, rather poitn to direct motion. Capt. Jacobs says, in 1857, "Has opened sensibly since 1853, being now an easy object, whereas then, under the most favourable circumstances, it could only just be discerned as not round."

THE MAMMALS AND BIRDS OF BURMA[1]

DURING the last few years of his life, the late Mr. Edward Blyth—whose death on December 27th 1874 we referred to on the following week—devoted much of his time to the production of a Catalogue of the Mammals and Birds of Burma. This he had originally commenced as a sketch of the Natural History of Burma, to form a chapter in a work on that country by Sir A. Phayre; but as he had gone too exhaustively into the subject for that purpose, Sir Arthur, on receiving the manuscript after its author's death, handed it over to Mr. Arthur Grote, with the view of its being published in the "Journal of the Asiatic Society of Bengal." To this the Council of the Society willingly assented, the result being that Blyth's posthumous "Catalogue of the Mammals and Birds of Burma" has appeared as an extra number of that journal, with an interesting and detailed biography by Mr. Grote. Different authors, with notes and additions, edit the different sections. Dr. John Anderson, the present curator of the Indian Museum of Calcutta, has undertaken the Mammals, with the exception of the Bats, which have been placed under the charge of Dr. G. E. Dobson; whilst Lord Walden edits the Birds. The editorial notes are all inclosed within brackets, so that there is no difficulty in distinguishing the author's own views. Without the notes and additions the work would not have been a complete one; as it now appears, it is an exhaustive account of the mammali- and avi-fauna of the Burmese portion of our Indian Empire.

Mr. Blyth's peculiar power of perceiving specific differences, together with his general scientific acumen, had full opportunity of displaying themselves when he in 1841 undertook the charge of the mass of unassorted material, in the forms of skins and bones, accumulated at Calcutta by the labours of Messrs. Hodgson, Cantor, and others. His thorough study of these enabled him to employ to the greatest advantage the opportunities which occurred to him of visiting Burma, which he did on several occasions, between 1860 and 1862. The results of these are embodied in the work under consideration, which as a simple catalogue would have been valuable, but is made doubly so by the extremely instructive comments which accompany many of the descriptions, and indicate how acute were the powers of their author as a naturalist. This may be further proved by the fact that of the 129 species of mammals known to inhabit Burma, thirty are recognised by names given by him.

As a point to which we would take exception we must refer to the name by which the author designates the "Ear-fringed Rhinoceros," first described by Mr. Sclater, from a unique specimen now living in the Zoological Gardens in the Regent's Park, as *Rhinoceros lasiotis*. It happened that Dr. Gray had given the name *R. crossii* to the owner of a rhinoceros horn, 17 inches in length, the shape of which was different from that of any known species. Why, when a new species is discovered, the horn should be assumed to be one of those belonging to it, is far from easy to understand, and Mr. Blyth gives no reasons for his nomenclature. He does place a note of interrogation after the name. If we remember correctly, the stuffed specimens of *R. sumatrensis* in the British Museum bear the name of *Ceratorhinus crossii*.

METEOROLOGY AT MELBOURNE[2]

THESE first three volumes of the new issue of the results of the meteorological observations carried on in Victoria under Mr. Ellery's direction, give copious details of all the work done at Melbourne, the chief observatory of the colony, the means and extremes of barometer and thermometer at from six to ten stations, and the amount and days of the rainfall at from twenty-six to thirty-four stations, the latter being the number of rainfall stations in 1874. To these are added, copious and very valuable *résumés* from all the thirty-four stations, of electrical phenomena, hail, frost, snow and sleet, fog, hot winds, storms of wind, auroras and earthquakes, most of which form so important elements in the climatology of Victoria.

The daily results for pressure, temperature, and evaporation, which are printed for Melbourne from observations made at 6 and 9 A.M., and 3 and 9 P.M., have been "corrected" so as to render their values, and those derived from them, equivalent to those deduced from hourly observations, presumably from the hourly values determined by Dr. G. Neumayer. This method of publishing results is objectionable particularly as regards daily observations; and even as regards monthly means, it is not free from serious objection, because, owing to the varying limits of the daily oscillations, this method of correcting observations must frequently mislead.

The anemometrical results for Melbourne are extremely valuable. In the summer months southerly winds and in the winter months northerly winds largely preponderate. Thus in 1874—while in January northerly winds (N.E., N., N.W.) showed a percentage of 11·3, southerly winds (S.E., S., S.W.) showed a percentage of 74·0; in July, on the other hand, the numbers were, northerly, 58·9, and southerly, 23·2. Again, in July, the three hours of the day showing the least velocity of the wind are 4 to 7 A.M., the mean being 7·2 miles per hour, and the three hours of greatest velocity noon to 3 P.M., the mean being 11·8 miles. But in January the three hours of least velocity are 3 to 6 A.M., the mean being 6·3 miles, and the three hours of greatest velocity 2 to 5 P.M., the mean being 15·8 miles. Hence in summer, even though storms of wind are then least frequent, the maximum daily velocity of the wind which occurs two hours later, is 4 miles greater an hour, being the direct result of the powerful action of the sun on the heated plains of the interior of Australia. It is to be hoped that in future issues Mr. Ellery will be able to add to these invaluable tables, a table showing the mean hourly variation in the direction of the wind for each month, a climatological datum of the first importance in Meteorology to which we have recently drawn attention in reviewing the reports of Toronto and Habana.

To each month's results are added the barometric, thermometric, hygrometric, and rain averages for eight of the stations, and since nearly all these averages are for periods varying from eleven to sixteen years, some interesting conclusions of a general character may now be drawn applicable to the whole colony. Thus in January the average pressure at 32° and sea-level is 29·962 inches at Cape Otway, on the coast, and 29·893 inches at Sandhurst, in the interior; but in July the averages are respectively 30·042 and 30·110 inches. These results show a diminution of pressure during summer in advancing inland, and an increase in winter, a distribution of atmospheric pressure in accordance with the prevailing winds in these seasons. In January the mean temperature varies from 60°·6 at Cape Otway to 70°·8 at Sandhurst; and at Beechworth, which is still more decidedly inland, the mean temperature is 2°·0 above that of Sandhurst, though it be fully 1,000 feet higher. At Cape Otway the difference between the coldest and warmest months is 13°·4, whereas at Sandhurst it is 25°·1.

The mean annual temperatures of Cape Otway 54°·7, and Portland 61°·5, call for examination. Cape Otway and Portland, which are nearly in the same latitude, both on the coast and only about fifty miles apart, show thus a difference in their mean temperatures of 6°·8, or a differ-

[1] "Catalogue of Mammals and Birds of Burma." By the late E. Blyth, C.M.Z.S. "Journal of the Asiatic Society of Bengal," new series, vol. xliii. Part 2.

[2] Results of Observations in Meteorology, Terrestrial Magnetism, &c., taken at the Melbourne Observatory during the years 1872, '73, '74, with Abstracts from Meteorological Observations obtained at various Localities in Victoria, under the superintendence of Robert L. J. Ellery, Government Astronomer.

ence equal to that between Greenwich and Montpellier in the south of France—a difference which might possibly arise from extraordinary and diverse ocean-currents—but to such a supposition current charts give no support. The publication might be rendered even still more useful by including among the means those of the maxima and minima of temperature, and those at the hours of 9 A.M. and 3 P.M. for pressure and temperature at all the stations, and by indicating on the map the whole of the stations from which observations are given in each year's publication.

AMERICAN-INDIAN STONE TUBES AND TOBACCO-PIPES

DURING the summer of 1873, I found a single specimen of a stone tube, that had been split throughout its entire length, as seen in Fig. 1. Since then, I have had an opportunity of examining several specimens found in New Jersey, and fortunately found two in the locality of my principal labours, in gathering up the scattered relics of the aborigines.

Fig. 1 is made of beautiful veined green and black slate, is six and one-eighth inches in length, slightly oval, and has been highly polished. The bore, which is exactly half-an-inch in diameter, is circular, uniform and direct. The drilling has evidently been accomplished by the use of a reed with sand and water, and the circular striae are visible throughout the length of the perforation. This drilling is the more interesting from the fact, that the work, commenced at one end, has been continued to the other, and not from either end to the middle, which latter method (and much the more common one) produces an hour-glass contraction at the point of juncture of the two drillings. Six or seven inches, however, was not the maximum depth attempted at drilling in one direction. Prof. Wyman, in "Fifth Report of the Peabody Museum of Archæology,"

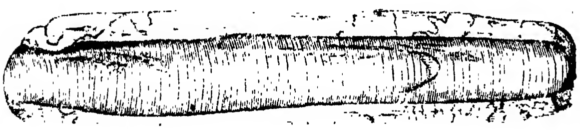

FIG. 1.—One-half natural size.

p. 13, describes "a cylindrical tube of soap-stone, twenty-two inches long and two inches in diameter, tapering somewhat at either end. This had been drilled from opposite ends, but the two perforations not coinciding, they passed by each other, the bores communicating laterally." We have in this implement, therefore, a single bore at least twelve inches long; which is probably the maximum length, for it is difficult to conceive of a stone to be of greater length than two feet, being of any use.[1] This is about the maximum of the non-perforated cylindrical stones called pestles; but which probably had other uses than that name implies.

Fig. 2, represents a quite common form of ornamental stone implement, but which, unfortunately, are seldom found except in very fragmentary condition. This specimen measures six and seven-eighths inches in length, by eight inches, lacking three-sixteenths, in breadth. The mineral is a soft sandstone, smoothed but not polished, and free from all attempt at ornamentation. Such specimens, when of less dimensions, have ordinarily been classed as badges of authority, gorgets, or if narrower, as double-edged axes, which could never have been their use, considering the soft material of which they are invariably made. As the perforation of this specimen exceeds in length that of the preceding, I am led to consider this simply as a "winged" tube, and to have had a use identical with such as above described (Fig. 1). While cylindrical tubes, plain or onamented, are quite abundant in

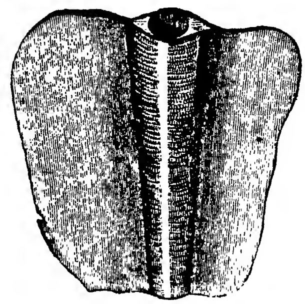

FIG. 2.—One-fifth natural size.

the southern and western states, these winged tubes appear to replace them in the northern and middle states.

Figs. 3 and 4 represent two specimens of tubes, that are of much interest, in that, while of the same general character as the preceding, they have not been bored; but are made of clay which has been moulded when soft, about a straight cylinder, presumably of wood, and then baked very hard. The exposure to fire would necessarily char, if not consume, the encased wood, and so leave a perforation in the clay when baked. This tube has then been brought to its present shape by scraping, and the ornamentation lastly carved upon it. In both specimens, the projective figure has been broken off, but the remaining fragment in Fig. 3 suggests the figure of a mammal, and that of Fig. 4 possibly a human head. On the tube, Fig. 3, will be noticed five short parallel lines. Such rows

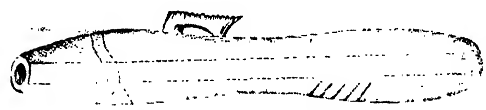

FIG. 3.—One-third natural size.

of short deeply engraved lines are very characteristic of the relics found in New Jersey (see figure of Marriage Emblem in NATURE, vol. xi., p. 436), and are probably record marks, but of what, on an implement like this, it is difficult to conjecture. The general shape of these tubes, and their diameters render it quite certain that they are not simply the stems of clay smoking-pipes.

These two specimens were found in the same grave, associated with the ordinary weapons of the aborigines; axes, spears, and arrow-points.

Fig. 5 represents a stone tube of a pattern quite different from any of the preceding. It is made of very soft soap-stone, is quite smooth, and accurately outlined. It is four and three-fourths inches in length; one and one-fourth inches in width at the broad, trumpet-mouthed end, and half-an-inch in diameter, where broken. The

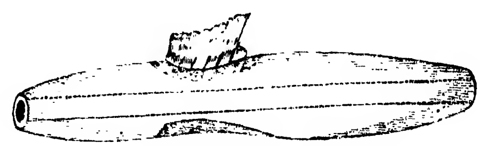

FIG. 4.—One-third natural size.

perforation is one-fourth of an inch in diameter, and of uniform size throughout. Such trumpet-shaped specimens occur elsewhere. Prof. Jeffries Wyman describes one in the Report above quoted, same page. He writes: "A fragment of another tubular instrument of the same ma-

[1] Mr. Evans, in his "Ancient Stone Implements of Great Britain," remarks that "the tubes of steatite one foot in length, found in some of the minor mounds of the Ohio Valley, must probably have been bored with metal." This depends altogether upon their age. New Jersey specimens of tubes have been found of nearly that length, which undoubtedly were made before the introduction of metal.

terial (soap-stone) appears to have had a long cylindrical body, and ends in an enlarged and trumpet-shaped mouth, and possibly was used as a horn."

Fig. 5 has faintly engraved upon it a serpent, or what appears to have been one. This representation of a serpent, and the figures on the specimens, Nos. 3 and 4, have probably the same object. Either they represent the owner, the name of the object being that of the possessor of the tube; or, if they were used solely by the sorcerers as "medicine tubes,"[1] wherewith they blew away disease, then the serpent in the one case, and the figures, now undeterminable, on Figs. 3 and 4, were the "gods" or "devils," through whose inspiration the "doctors" effected their cures. How to explain the meaning of the "wings," of Fig. 2, is certainly difficult, if I am correct in my surmises concerning the other specimens; but these may simply be meaningless ornamentation, just as the broken specimen, Fig. 1, when entire, was just as effectual as any in blowing away disease, provided the suffering patient was made to believe so, by entertaining faith in his physician.

A few words in conclusion upon the use of stone drills in boring through stone. There is, in the museum of the Peabody Academy at Salem, Massachusetts, several hundred specimens of stone-drills, all of jasper, and varying greatly in length. These specimens, collected by the writer, have been frequently experimented with, and they are found capable of very rapidly drilling in the minerals of which these tubes and "gorgets" usually are made. And when sand and water are used in addition, it is not extremely difficult to drill in mineral of like or greater density. Stone-drills, such as here referred to, are not flat, like a slender arrow-point, but quadrangular (diamond-shaped) when viewed in section. The points of the few

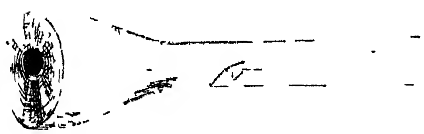

Fig. 5.—One-half natural size.

perfect specimens I have found, were mostly very highly polished, and the sides showed clearly, in some specimens, the action of sand. These drills vary from one to seven inches in length, and from three-sixteenths to over an inch in diameter; or rather the bores they made, had these measurements. Figures of such drills are given in vol. vi. of "American Naturalist," pp. 205—214; also by Mr. Evans, in "Ancient Stone Implements of Great Britain," p. 290, Fig. 230. None of the drills, however, mentioned by Mr. Evans, are large, and are capable only of perforating thin plates of stone. While convinced that a reed, with sand and water was most frequently used in deep bores, I can see no reason for doubting that stone-drills were also used; for such specimens are by no means rare, and no other use can be suggested for them.

The various forms of stone implements found in New Jersey, however specialised, appear to be all traceable to others, far less elaborate, and these ruder patterns, as I have endeavoured to show, are now found at such depths, as a mile, that they may safely be considered as of greater antiquity and the forerunners of the more finished types, the true surface-found specimens. From this fact I have concluded that the red man of the Atlantic coast of North America reached our shores a palæolithic savage, and when discovered by the Europeans had attained to the neolithic stage of culture.

There is one form of stone implement (and only one) that offers an exception to the assumed rule that the ruder antedate the more finished specimens; that is, the smoking pipes. There are no rude or palæolithic pipes occurring in New Jersey, nor, I believe, in any portion of the country. They are all more or less polished and so wrought that they must be classed as a neolithic form of stone implement. Among the chipped unpolished implements of the river gravels I have been unable to find any specimen that could be imagined even to be connected with the custom of smoking. There is, however, abundant evidence of improvement in the flint-chipping art having been attained by the red man while an occupant of this country, readily traced in the axes, arrowpoints, and other forms of weapons and domestic implements; and such advance is not seen in the fashioning of pipes.

For the reasons already stated, I conclude that the custom of tobacco smoking was introduced or established after the red man had attained to the higher division of the Stone age; and that the first pipes were of perishable materials. Such pipes must, I think, have been of wood. Succeeding the use of this, which was necessarily inconvenient, there is reason to believe that a rude clay bowl was attached to the stem, a mere shapeless lump of clay that they would soon learn was rendered somewhat more durable by the exposure to heat. The use of clay bowls might have arisen, too, by the hardening of the earth simply, if the first receptacle for the tobacco was simply a depression in the ground, to the bottom of which was

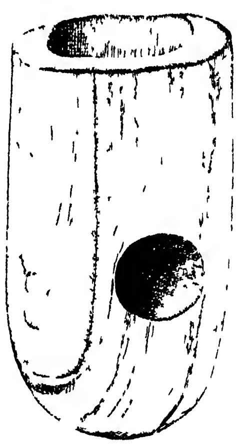

Fig. 6.—Plain Pipe Bowl, natural size.

placed one end of the reed, through which the smoke was drawn to the mouth. However this might have been, I believe I have found fragments of pipes so rude in their shape and coarse in their composition as to warrant the belief that such specimens were the forerunners of the durable stone pipes that now occur in scanty numbers among the relics of the red men of New Jersey.

Inasmuch as the use of clay for pipe bowls was not abandoned, there of course exists a vast range of excellence in the workmanship displayed in their manufacture, and many of the fragments that I have found were as artistically ornamented and made of as carefully prepared clay as others were rude and of the coarsest material. These rudest specimens are never found in graves, and seldom met with except when deeply embedded in the soil, suggesting that they were in use before the custom of burying the smoking pipes of the dead with them was established, and therefore that they antedate the more elaborately finished specimens, which are occasionally found among the deposited relics of "grave-finds;" but such an occurrence is rare in comparison with the presence of stone pipes under similar circumstances.

While the pipe bowls of stone exhibit a considerable range in the excellence of their finish, there is not sufficient variation to warrant one in considering the more rudely finished specimens as the older. They are all well

[1] Venegas (Nat and Civil Hist of California, vol. i, p. 97. London, 1759) states: "They (medicine men) applied to the suffering part of the patient's body the *chacuaco*, or a tube of a very hard black stone; and through this they sometimes sucked, and other times blew." Quoted by C. C. Jones, junr., in "Antiquities of Southern Indians," p. 363.

made and admirably adapted to their peculiar use. Ornamentation was confined, in the vast majority of cases, to the natural markings of the mineral, and not derived from any carving as is so marked a characteristic of the pipes of the mound-builders. Fig. 6 represents a perfect specimen of such plain pipe bowls as I have described. There is no line, straight, curved, or zigzag upon it. The red man who made this specimen had utility solely in view; unless the choice of mineral was considered, as giving beauty to the finished pipe. The material of the specimen figured is a pale green slaty rock, veined with black. The variation in shape of such pipe bowls is of course considerable; and supposing each individual to have made his own pipe, the shape was in each case decided by the maker's fancy solely. As in the case of arrow-points, of which a score of patterns occur, so with pipe bowls. One will scarcely find two precisely alike; yet the "family likeness" is very strongly marked.

There does occur, however, a second form of smoking pipe, but much more sparingly than the preceding, differing greatly, both in size and shape. While the two patterns occasionally approach in general outline, they do not do so sufficiently to warrant our considering the one to pass into the other form.

This variety of pipe, of which Fig 7 is an example, is well known as the calumet or "peace-pipe." The bowl

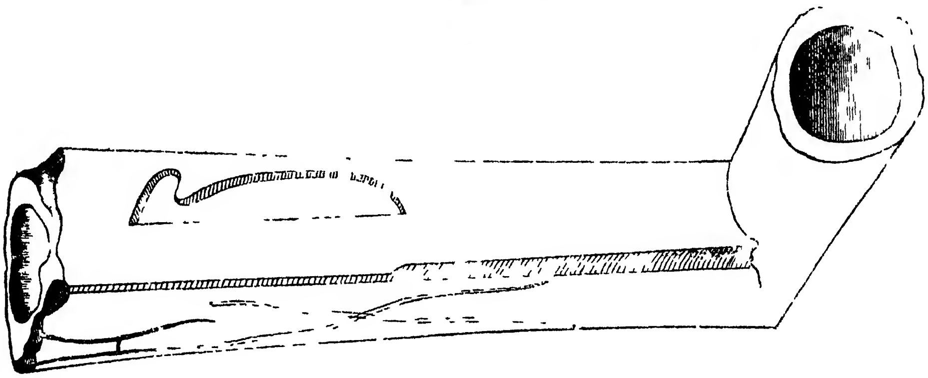

FIG. 7.- Calumet, natural size

in this case, as a rule, is much smaller, and the labour of the maker has been expended upon the stem-like base, which in every specimen I have seen has been quite elaborately ornamented. The specimen figured is not as much carved as many, but being quite perfect, is represented in preference to fragments of others.

I believe no specimens of "animal pipes," such as are found in the Mississippi valley, have been found in New Jersey, which fact is interesting, as there is much reason for believing that when the mound-builders occupied the western valleys the red man was already occupying the Atlantic coast; and doubtless some trading was carried on between the two peoples. Therefore, it would be natural to expect that such pipes should occur among our Indian relics; or at least that there was sufficient knowledge concerning them to suggest to the coast Indians the idea of imitating them; but there is no trace of such imitation I believe. It is their smoking pipes alone, of all their productions in the flint-chipping art, that are dissimilar.

Through the writings of the earlier missionaries we learn of the peculiar uses and significance of these calumets, which formed so prominent a feature on all important occasions; but whether they were introduced by some other race with whom the red man came in contact, or originated *de novo*, it is impossible to determine; but it is quite certain that the specimens so far brought to light do not enable us to trace the evolution of the calumet from the simpler form of pipe.

Trenton, N.J., U.S.A., May 6 CHAS. C. ABBOTT

NEW METEOROLOGICAL LABORATORIES AT MONTSOURIS

M. MARIÉ DAVY, Director of Montsouris Observatory, has organised, partly at the expense of the City of French Government, partly at the expense of the City of Paris, a chemical and microscopical laboratory for the analysis of all the matters in suspension in the air of Paris, both quantitatively and qualitatively. A certain quantity of air is constantly aspired by an aspirator in continued operation. The ozone acting on iodide of potassium and starch liberates iodine. The quantity of ozone liberated is measured by a titrated solution of arsenite of sodium. The matters in suspension are collected on a glass plate, and the crop is placed under the object-glass of a powerful microscope magnifying 1,000 times. The principal forms are drawn and plates are executed and published monthly in the Transactions of the establishment. The analysis of rain-water is conducted on the same principles, and the results of chemical analysis are calculated and compared with the wind and other atmospheric circumstances.

We are indebted to M. Marié Davy for the principal results of the month of February, the first period for which the whole system has been put into complete operation.

The electrical department has been fitted up, after a preliminary trial, and has been in working order for some time. In order better to illustrate the importance of these researches we take the liberty of altering the figures in order to give the results in round numbers for the whole area of Paris within the fortifications. The surface is about 80,000,000 square metres. In February 1876 the quantity of atmospheric water was 4,500,000 cubic metres. This is about double the average, but in some years on record the quantity was even larger, in 1776 a century ago, it was more than 6,500,000 cubic metres. In taking as an average the analyses of rain-water at Montsouris, the 4,500,000 cubic metres contained 4,700 kilogrammes of nitric acid and 10,700 kilogrammes of ammonia. This mass of nitric acid is supposed to have been produced by electrical reactions in the atmosphere, and ammonia only partly, as Montsouris is in the southern part of the city, close to the fortifications.

The 4,500,000 cubic metres of rain water were also proved to contain 172,000 kilogrammes of organic matter, and 88,400 kilogrammes of metallic salts or products. A number of organic matters have been found

to be composed of spores, parts of animalculæ, and even living infusoriæ. Amongst the metallic salts we must mention particles of meteoric iron, evidently of cosmic origin. It is contemplated by the city of Paris to establish similar observations in several parts of the city, and the careful comparison of these analyses will prove invaluable for establishing a number of most interesting facts having a bearing on the welfare of inhabitants, as well as on the elucidation of important scientific problems.

It is also contemplated to make use of aëronautical ascents to test the air at any altitude accessible to a balloon with horizontal glass plates covered with glycerine. The moisture of the clouds is to be condensed on glass tubes which will be refrigerated.

The ozone testing and measuring has produced also startling facts. Although the quantity of ozone is very minute, amounting to only a few milligrams per 1,000 cubic metres, it has been proved that on Feb. 27, the day of the ozone maximum, a quantity of 900 kilog. was floating over Paris, if we suppose that the quantity was the same as at Montsouris in the whole stream of air passing above up to the altitude of 1,000 metres.

These results are only a sample of those which may be expected from the constant application of the magnificent system which is now brought into operation for the first time, and of which it will be possible to say, *Vires acquirit eundo.*

W. DE FONVIELLE

NOTES

THE following are the arrangements for the Free Lectures in connection with the Loan Collection of Scientific Apparatus for the next few weeks. The lecture hour is eight P.M. Saturday, June 17, Mr. W. H. Preece on Telegraphic Instruments; Monday, June 19, Mr. Kempe on the Application of Linkages to Machinery; Saturday, June 24, Capt. Abney, F.R.S., on Photographic Printing Processes; Monday, June 26, Dr. Schuster on Ampère's and Faraday's Instruments; Saturday, July 1, Mr. W. C. Roberts, F.R.S., Graham's Apparatus and what he did with it; Monday, July 3, The Right Hon. Dr. Lyon Playfair, C.B., F.R.S., Otto von Guericke's and Black's Instruments; Saturday, July 8, Dr. Gladstone on the Instruments lent by the Royal Institution.

ON the 1st inst. the Society of Arts of Geneva celebrated the first centenary of its existence. Founded in 1776 by H. B. De Saussure and some of his friends, it has continued ever since to render real service to Switzerland in the departments of Arts, Industry, Commerce, and Agriculture. Without having any direct connection with science, it has always, however, been associated with it, and all the scientific men of Geneva have from time to time taken a share in its proceedings; the Pictets, De Candolles, De la Rives, and other well-known names, have at various times been presidents. A prize founded by Aug. De la Rive, to be awarded to the discovery most useful to Genevese industry, is intrusted to the care of the Society. In order worthily to celebrate the centenary, the Society had announced various competitions in the different branches with which it is connected, and which appealed to all manufacturers of horological instruments. The nature and terms of this competition we announced last October (vol. xii., p. 525). It was an international competition in chronometry, in which there was a large number of competitors, and of which the results have been now made known. A Prize of Honour was awarded to M. Ulysse Nardin, of Locle, Neuchâtel; six equal First Prizes were awarded to M. H. R. Ekegrin, of Geneva, Messrs. Parkinson and Frodsham, of London, Messrs. Badollet and Co., Geneva, Bredard et Fils, Geneva, M. Ed. Perregaux, of Locle, and M. Fritz Piguet, of Geneva; other awards were likewise made. After the general meeting and the distribution of prizes, a banquet was held, at which about four hundred members of the Society were present; this was followed by a conversazione on the terrace of M. Th. De Saussure, grandson of the celebrated naturalist, the founder of the Society, on the very place where the first meeting was held a century ago.

AT the meeting of the Royal Geographical Society on Monday, Sir Rutherford Alcock, the new president, in the chair, a paper by Mr. E. D. Young, R.N., was read, on a journey to the northern end of Lake Nyassa. The cruise round Lake Nyassa had occupied a month, and the area was much larger than Dr. Livingstone thought, the north end extending to 9·20 S. lat. In most parts it was very deep, and in several places no bottom could be found with 100 fathoms of line. A range of mountains nearly 100 miles in length, extended above the lake, some reaching an elevation of 10,000 or 12,000 feet. There were also numerous rivers running into the lake, but none navigable for any distance. At some parts there were numbers of villages built on piles in the lake; many people in other parts living on barren rocks. Mr. Young added that he intended to be back to England in a few months, and would in the meanwhile make a more perfect survey of the lake and give the results to the Geographical Society on his return. A paper on "The Valley of the Tibagy, in Brazil," by Mr. T. B. Wither, C.E., was also read. The author of the paper was engaged in conjunction with others, in August, 1871, in exploring that section of the Ivahy Valley which lies between Colonia Theresa and the Corredeira de Ferro, or "Iron Rapid."

THE University of Oxford proposes to confer the degree of D.C.L upon the following, among others:—Prof. W. H. Miller, F.R.S., Prof. J. Clerk Maxwell, F.R.S., Dr. Samuel Birch, and Lieut. V. L. Cameron.

THE Oxford University Bill was read a second time in the House of Commons on Monday. In the debate which followed there was nothing worthy of comment.

THE annual conversazione of the Society of Arts will be held at South Kensington Museum on Friday, the 23rd inst.

IN a recent issue of the Italian medical journal *L'Imparziale* laments that the unjust and ridiculous accusations of a number of strangers resident in Florence and of an exceedingly small minority of the inhabitants should have induced Prof. Schiff to accept the chair which has been offered to him at Geneva. The loss to physiology in Italy will be so great that, according to a communication in the *Daily News*, the *Bersagliere* believes that the Minister of Public Instruction will use every endeavour to make the illustrious physiologist withdraw his resignation.

EXCELLENT accounts have been received from the German North Asiatic Expedition, which has arrived as far as Semipalatinsk, in Siberia, and has obtained living specimens of the large Argali sheep (*Ovis ammon*) of Linnæus.

THE veteran ornithologist, Dr. Hartlaub, has in preparation a new work upon the Ornithology of Madagascar and the adjacent islands. Since Dr. Hartlaub's original memoir on this subject was published in 1861, since which time Pollen, Van Dan, Crossley, Grandidier, and others, have done much to increase our knowledge of the avifauna of Madagascar.

WE hear from Sidney that the sum of 800*l*. had been raised towards Signor D'Albertis' expedition up the Fly River, New Guinea; and that he was intending to start from that city on the 19th of April with the steam-launch loaned to him by the Government of New South Wales.

WE regret to hear that the strife at Sidney about the dismissal of Mr. Krefft from the post of Curator and Secretary of the Australian Museum is not over. The subject came before the Legislative Assembly on the 6th of April, and provoked an

angry discussion. Mr. E. P. Ramsay has been installed by the trustees as Mr. Krefft's successor, and is in full work; but the Supreme Court has decided that the trustees had no real authority to remove Mr. Krefft. Whatever the issue may be, everyone acquainted with the case must hold that Mr. Krefft deserves fair and liberal treatment as one of the few naturalists in Australia that have done good original work in spite of many surrounding difficulties.

ON June 7 a violent thunderstorm occurred at Valbonne, a large plain at a little distance from Lyons. The only objects struck were huts full of soldiers and arms, and the occurrence furnishes a good instance of the "power of points" and the attracting power of metals and living beings for lightning. Three tents were struck in succession. The occupant of the first was absent at the moment, and the effects were relatively slight, producing only the breaking of stones and dispersing of dust. In the second instance a soldier who was standing erect in front of one of the tents was struck; but the tent being located in the vicinity of an electric telegraph the lightning escaped by it, fired the wires, and broke a dozen poles. This may suggest a very easy method for protecting an encampment. The third flash struck a number of tents placed in a zig-zag line, doing much damage, several of the occupants being either killed or wounded. In one tent three men were killed and seven wounded. All of them were either touched in both legs or on the right side except one, who was wounded in the right eye. In another tent four men were wounded, all of them in both legs or in the left one. In other instances men were turned round in or heaved out of their beds. In all the instances referred to the men were lying on their beds, made of iron, and the sentry standing in front remained unhurt. In one tent a man, who was lying between two men who were killed, escaped unhurt. The uniforms of the soldiers were perforated and exhibited small spots; one, four centimetres in diameter, entirely sulphurised. A chemical analysis will be made of this part of the uniform, and the result communicated to the Academy of Sciences.

AT a meeting of the Cymmrodorion Society held last Friday, in the Memorial Hall, Farringdon Street, Prof. F. W. Rudler, F.G.S., read a paper on "Natural History Museums, with Suggestions for the Formation of a Central Museum in Wales."

THE boring of the shafts for the Anglo-French tunnel is progressing favourably. A pump has been erected for the draining of the works. Water has been already met with in abundance, although the depth reached is only 40 feet. The intended level is 60 feet further down.

THE Edinburgh Town Council, it is stated, have agreed to apply to the Government for aid to the building fund of the University extension scheme, and to memorialise in favour of a parliamentary grant. The Council had previously subscribed 1,000 guineas to the fund on their own account.

THE Geographical Society of Paris has received good news from the Gaboon expedition. Lieut. Brazza and M. Marche have located themselves at Okanda, 500 miles from the mouth of the Ogowe, and are establishing permanent settlements and ready means of communicating with the factories on the coast. They lost a part of their baggage and goods in crossing rapids, but having been enabled to send messengers to the French Gaboon settlement they will recover from their losses and will proceed further in the untrodden region.

ON June 8 the French Society of Amis des Sciences held its annual meeting at Paris. M. Bert gave a lecture on the *Zenith* balloon catastrophe in connection with the inhalation of oxygen. This Society was founded by the Baron Thenard for assisting scientific men in their work and their families after their death.

THE French Society for Encouragement of National Industry had to vote this year the great Prony prize for the most useful invention in mechanics discovered during a certain number of years. The award was made to M. Henry Giffard, of Paris, the aëronaut, for the invention of his injector, used in all locomotives. The invention is fifteen years old, and the patentee has realised through this his single invention a fortune falling very little short of half a million sterling.

WE take the following from the *Geographical Magazine*:—Dr. P. Ascherson left Benisuef for Medinet-el-Fayum, on March 16, and started from the latter place on the 24th, *en route* for the Little Oasis, the botanical exploration of which constituted the object of his journey. On April 1 he reached Bauiti, the present capital of the Oasis parva, by the same route as that followed by Belzoni in 1816. This journey proved that no "Bahr bela ma" or old river-bed exists in that portion of the Libyan Desert. After an exhaustive exploration of the oasis, Dr. Ascherson started on May 1 on his return journey, travelling by an entirely new route, and reaching the Nile at Samalut. The botanical exploration of the oases of the Libyan Desert begun two years ago by Dr. Ascherson, whilst a member of Rohlf's expedition, has thus been terminated, and several facts of great interest have been ascertained during this last journey as regards the Fayum, as well as the Little Oasis. Several species of plants, met with far to the east and south-west, in Asia, but not in the Valley of the Nile, or in the deserts to the east of it, occur also in the oases. Some of the more remarkable of these plants are *Dianthus Cyri*, *Populus euphratica* (= *P. diversifolia* of Mongolia), and *Prosopsis Stephaniana*.

THE Society of Ethnology of Paris has proposed, for 1876, a prize to the best memoir on "The Slavonic Race, and Maps of the Countries inhabited by Slavonians." The prize will be awarded in December, and the memoir may be written in English as well as in French and in several other languages, not excluding Polish and Russian.

THE twenty-fifth Annual Educational Conference of the Society of Arts will take place on June 23, at 11 o'clock. The chair will be taken by Sir Henry Cole, K.C.B. With the view of giving special interest to the Conference this year, the Council have decided that the subject of adult education, especially in reference to technical instruction and its promotion by the action of the Government, shall form the principal subject for discussion.

PROF. E. QUETELET has written a brief notice in the *Bulletin* of the Royal Academy of Belgium, of the storm of March 12, 1876, which was the most violent hitherto observed at Brussels, the wind having reached the enormous pressure of 144 kilogrammes per square metre, or nearly 30 lbs. per square foot, and the barometer fallen to 28·560 inches at sea-level, having only once fallen below this point since the founding of the Observatory in 1833. We are glad to see that Dr. Buys Ballot is also examining this remarkable storm, which he will be able to do very fully owing to the number of registering barometers in operation at the Dutch Meteorological Stations.

IN the *Supplemento alla Meteorologia Italiana*, anno 1875 fasc. ii., there appears a very valuable paper, by P. F. Denza on the distribution of the rainfall in Italy during 1872. The paper, which is one of great ability, details the rainfall of tha year, comparing it where possible with the averages of pas years; and in consideration of the singular diversity with seaso of the rainfall of the different parts of Italy, the stations ar classed according to five zones, viz., Alpine, Pre-alpine, Ea Apennine, West Apennine, and Sicilian. The details of tl great rains of October 1872 are very interesting, the amou for the month being 40 inches at Pallanza, 41 inches at Crabbi

If the object is merely to raise water this can be done without the employment of either water-wheel or turbine. When a small quantity is required to be raised to a considerable height the Montgolfier ram is employed. No. 1,996, which I have before me, is a glass model of such a ram, but I fear it is too small to be visible, except to those who are very near to the table. You are, however, all aware that the principle of action consists in the sudden arrestment of a column of water flowing with a velocity due to the head. The water on being arrested performs two functions, a small portion raises an outlet valve, and thereby passes into an air-vessel against a pressure competent to drive the water up to the desired height; while the main body recoils along the supply pipe; then, the escape valve having opened the water that has recoiled, returns, a large portion passes out of the valve, and thus the velocity being fully established the escape valve shuts and causes another arrestation and a repetition of the working. This is an implement by which a large volume of water coupled with a low fall, can be made to raise a portion of itself to a great height. But there is a converse use of water, wherein the employment of a small stream of water moving rapidly (owing to its having fallen from a considerable height) is caused to induce a current in other water and to draw it along with itself at a diminished velocity but still with a velocity competent to raise the united stream to a less height, and in this manner many swamps and marshy lands have been drained.

This employment of the induced current as a prime mover is described by Venturier in the record of his experiments made at the latter end of the eighteenth century, and within the last few years Mr. James Thomson has applied the same principle with great success in his jet pump.

The next mode I shall notice of obtaining motive power from water, is also one where it operates by an induced current; this is the "Trombe d'eau," an apparatus wherein water falling down a vertical pipe, induces a current of air to descend with it. The lower end of the vertical pipe being connected with the upper side of an inverted vessel, the bottom of the sides of which vessel is sealed by a water joint, then the water dashing upon a block placed below the mouth of the pipe, is separated from the air, so that while the water descends and escapes from under the sides of the vessel, the air rises and accumulates in the upper part from whence it can be led away to blow a forge fire. These machines are described in Belidor's work.

The utilisation of the rise and fall of the tide is also fully described by Belidor, who gives drawings of channels so arranged that during both the rise and fall of the tide the wheel, notwithstanding the reversal of the currents, revolves in one and the same direction. The tide is a source of power which it is highly desirable should be utilised to a greater extent than it is; if we consider the enormous energy daily ebbing and flowing round our shores, it does seem to be a matter of great regret that this energy should be wasted, and that coal should be burnt as a substitute.

The last mode in which power may be obtained from water, to which I have to allude, is that of the employment of the waves.

Earl Dundonald, better known as Lord Cochrane, proposed by his patent of 1833 to utilise this power for propelling a vessel; this he hoped to accomplish by the use of cylinders containing mercury, the oscillations of which were to cause a vacuous condition in the cylinders, and thereby give motion to an air-pressure engine. Lately we have had produced before the Institution of Naval Architects, and also before the British Association at Bristol, the apparatus of Mr. Tower, by which the motion of the waves is to be utilised; a model constructed on this principle has driven, it is said, a boat against the wind at some two or three miles an hour.

The next kind of prime-movers in order of date to be considered, are those that are worked by the wind.

Although undoubtedly the propelling of a ship by sails, and even the winnowing of grain, must have long preceded the invention of a prime mover driven by water, yet the employment of the wind as a source of motive power for driving machinery, appears to be but of comparatively recent date. It is said that the knowledge of this kind of prime mover was communicated to Europe by the Crusaders on their return from the East, but it is difficult to see what foundation there is for this statement. It appears to be certain, however, that wind-motors were commonly employed in France, Germany, and Holland in the thirteenth century.

We can easily understand that in countries where water falls [illegible] streams are abundant, the windmill would not, owing to its uncertainty, be resorted to; on the other hand, in inland countries and in countries like Holland, where the streams are sluggish, and where there is a large amount of land to be drained, the wind, although still uncertain, would nevertheless be a valuable power, and therefore would be utilised.

Prime movers to be worked by the wind appear to have been made practically in only two forms, viz, the common one, wherein a nearly horizontal axle carries four or more twisted radial sails, and that one wherein the axle is vertical and the arms project from it laterally either as radial fixed arms, as curved fixed arms, or as arms having a feathering motion similar to that of paddle-wheels. Where the arms are straight and fixed, some contrivance must be resorted to to obtain a greater pressure of wind on one side than on the other.

Bessoni, in his work "The Theatre of Instruments and Machines," published at Lyons in 1582, describes a windmill with vertical spindle and curved horizontal arms, placed in a tower with a wind-guard, and by the drawing shows it working a chain-pump. Belidor also says, in Article 852 that windmills with vertical axles were well known in Portugal and in Poland, and he describes how that they work within a tower the upper part of which was fitted with a movable portion to act as a screen to one side of the mill.

I will not detain you by an allusion to the sailing chariot mentioned by my Uncle Toby in "Tristram Shandy," nor will I pause to describe the very modern one, that is to say, not more than about thirty years old, which was employed upon Herne Bay Pier. In fact this Exhibition gives but little encouragement to pursue the subject of prime-movers worked by wind, as I have not as yet come across in the Catalogue any apparatus illustrative of the subject.

It is to be regretted that the use of this kind of prime mover, the windmill, is on the decline. It is a power that costs nothing; the machinery can be erected in almost any situation; and although such a motor cannot by itself be depended on, being of necessity "as uncertain as the wind," it nevertheless might be commonly employed as an auxiliary to steam-power, diminishing the load upon the engine in exact proportion as it was urged by any wind which might happen to blow.

I may say, to the credit of our American brethren, that they employ on their sailing-ships a windmill known by the sailors as "The Sailor's Friend," to pump, to work windlasses, and to do all those matters which in a steam ship fall to the lot of the donkey-engine and steam winch, unless, as in a recent voyage in which all Englishmen have been so much interested, these duties were imposed upon the baby elephant.

There is one motor which may be put either into this class or into the next, where we consider the application of heat; I allude to the smoke-jack, but beyond recognising its existence as a prime mover, and a very early one indeed (it is to be found in Zoncas' work published in 1621), attention need not be bestowed upon it.

We now come to consider those prime movers which are worked by the immediate, and not by the secondary, action, of heat.

The direct rays of the sun have, for a very long time past been suggested as a means of obtaining motive power. Solomon de Caus in his work, published in 1615, describes a fountain which is caused to operate by the heat of the sun's rays expanding the air in a box and expelling the water by, through a delivery valve, the water from the lower part of the box. When the sun's rays have been withdrawn, the air, cooling, contracts, the suction valve, opens and admits more water into the box to be again displaced on the following day. He also gives a drawing of an apparatus where the effect of the sun's rays is to be intensified by a number of lenses in a frame. Solomon de Caus proposes these machines as mere toys to work an ornamental fountain, but Belidor, by Article 827, describes and shows a sun pump consisting of a large metallic sphere, fitted with a suction pipe and valve, and a delivery pipe and valve and occupied partly by water and partly by air, the suggestion being as in the case of Solomon de Caus, that the heat of the sun in the daytime expanding the air should drive the water into a reservoir, while the contraction of the air in the night-time should elevate the water by the suction pipe and charge the sphere for the next day's work. In modern times, we know, some attempts to obtain practical motive power from the direct action of the sun have been made, and notably by Capt. Ericsson.

The temptation to endeavour to bring into practical use a machine of this character is very great. We were told by

President, in a lecture delivered by him to the British Association at Bradford, that the solar heat, if fully exercised all over the globe, supposing that globe to be entirely covered with water, would be sufficient to evaporate a layer 14 feet deep of water per annum. Now assuming 10 lbs. of water evaporated from the temperature of the air into steam by the combustion of 1 lb. of coal (a much larger result than unhappily is got in regular work), this would represent an effect obtained from the sun's rays on each acre of water equal to the combustion of 1680 tons of coals per annum, or to about 92 cwt. of coal per acre per twenty-four hours; or enough to maintain an engine of 200 gross indicated horse-power day and night all the year round. When, however, we consider the effect of the sun, not upon the surface of water but upon the earth, and deal with its power of producing heat-giving material, the result compares very unfavourably with the work done by the sun itself; and this, no doubt, arises first, from the fact that the sun is frequently obscured, and second, from the fact that a large portion of the energy of the sun is spent in evaporating moisture from the ground, and not in the direct production of combustible material. I have found it extremely difficult to obtain any reliable data as to the weight of fuel grown per acre per annum. If we take the sugar cane, we find that in extremely favourable cases as much megass and sugar together are produced as would equal in calorific effect about five tons of good Welsh coal. Coming to our own country and dealing with a field of wheat, the wheat and straw together may be taken as being equal probably to about two tons of coal as a maximum. The statements made to me with regard to the production of timber per acre per annum, when grown for the purpose of burning, are very various; but the best average I can make from them is that in this country there is produced as much wood as is equal in calorific effect to about 1½ tons of good coal per acre. Comparing these productions of heat-giving material with the energy of the sun, as shown in the evaporation of water, one shows how tempting a field is that of the direct employment of the solar rays as a source of power; more especially, when it is remembered that those rays are obtained from week to week, and year to year, without having to wait the tardy growth of the fuel-destined tree.

I will now ask you to consider with me the prime movers that owe their energy to the heat developed by the combustion of some ordinary kind of fuel—coal or wood. Passing by as a mere toy and not an actual prime mover, the reactionary steam sphere, the eoliopile of Hero, I will come at once to those simple forms of heat-engine (whether worked by steam or the expansion of air), by which water was to be raised. Solomon de Caus, in his work of 1615, already mentioned, says that if you fill a globe with water and have in its upper part a pipe dipping nearly to the bottom, and if you put the globe upon the fire the heat will cause the expansion of the contents, and the water will be delivered in a jet out of the tube.

The Marquis of Worcester in his "Century of Inventions," published in 1659, makes, as is well known, a similar proposition, but it does not appear that these machines were seriously contemplated for practical use. Papin (I take Belidor's Article No. 1,276 as my authority) in 1698 (as appears in his pamphlet of 1707) experimented by order of Charles the Landgrave of Hessen Cassel with the view of ascertaining how to raise water by the aid of fire. But his experiments were interrupted and he did not resume them until Leibnitz, by a letter of Jan. 6, 1705, called his attention to what Savery was doing in England, sending him a copy of a London print of a description of Savery's engine. This engine, which of course is well known to you, is illustrated by a model in this collection, and now on the table before me. Savery employed a boiler, the steam from which was admitted into a vessel furnished like the sun-pump of Belidor with a suction pipe and clack and a delivery pipe and clack; the steam being shut off, cold water was suffered to flow over the vessel, a vacuum was made and water raised into the vessel, which was expelled out of the delivery pipe upon the next admission of steam, the cocks being worked by hand. This machine came into very considerable use and was undoubtedly the first practical working steam-engine. It had, however, the defect of consuming a large quantity of steam, as the steam not only came into contact with the cold vessel but also with the surface of the water in that vessel. Papin, as we know, obviated a portion of his loss by the employment of a floating piston placed so as to keep the steam from actual contact with the surface of the water.

We have in the collection, No. 2,007, a cylinder from Hessen Cassel, said to be of the date of 1699 and to have been intended for employment in Papin's machine, but it is difficult to say for what part of the apparatus it could have been designed, inasmuch as the cylinder is provided with a flange at one end only and no means, so far as I can ascertain, exist for closing the other end. You will see from the diagram that which no doubt is already well known to you; Papin did not propose to condense the steam, and by its condensation to "draw up" the water (to use a familiar expression) but intended that the vessel should be charged by a supply from above, and, that the steam should be employed only to press on the floating piston and to drive the water out. Papin, however, hoped to use his engine, not merely as a water-raiser, but as a source of rotary power by allowing the water to issue from the air vessel, so as to impinge upon the pallets of a water-wheel and thus produce the required revolution.

(To be continued.)

SCIENTIFIC SERIALS

American Journal of Science and Arts, May.—Mr. Holden here collates various observations made on nebula M 17 (the figure of which is like that of a Greek capital Omega) from 1833 to 1875. The drawings show that the western end has moved relatively to its contained stars, and always in the same direction. It may be a veritable change in the structure of the nebula itself or the bodily shifting of the whole nebula in space.—Mr. Trowbridge states that the application of thin plates of soft iron on the poles of two straight electro-magnets, with bundles of fine iron wires for cores, increases the strength of the spark at the poles of two secondary coils surrounding the electro-magnets, 400 per cent. The length of the spark is increased 100 per cent. (but this is only manifested by using Leyden jars of large capacity with the secondary circuit). Instead of distributing the fine wire of a Ruhmkorff coil on a straight electro-magnet, as at present, it should be distributed equally on two straight electro-magnets whose poles are provided with armatures of bundles of thin plates of soft iron.—Mr. Wilson having applied infusorial earth to land sown in wheat, afterwards treated some of the wheat straw with nitric acid, and found that the siliceous remains consisted almost wholly of the shields of diatomaceæ, the same as found in the infusorial earth (only the larger discs, in their perfect form, being absent). It would appear that simple or compound silicates are useless as fertilising agents, and that silica can enter the plant only in the free state.—In the first portion of a paper on the solid carbon compounds in meteorites, Mr. J. Laurence Smith, after noting that in carbonaceous meteorites the mineral constituents are mainly the same as in the so-called common type of meteoric stones (viz., olivines, and pyroxenes, differing only in the more or less compact form of these minerals), shows, that even in the carbonaceous constituent they are strongly linked even to the iron meteorites.—Mr. Fontaine continues his account of the conglomerate series of West Virginia; Mr. Dana describes new forms of staurolite and pyrrholite; and we also find chemical notes on phosphorus oxychloride, and the oxydation product of glycogen with bromine, silver oxide, and water.—A simple and very accurate method of testing the unison of two forks is (according to Mr. Spice) by holding them *together* over their proper resonant column; if the forks be *very* nearly in tune, beats will be perceived succeeding each other at long intervals, or the sound will merely swell out again very slightly after it has nearly died away. When the forks are absolutely alike, there will be a gradual decrease of sound down to silence, without any reinforcement at any time.

THE *American Naturalist* for May commences with an article by the Rev. S. Lockwood, on Animal Humour. Prof. Asa Gray writes on Wild Gooseberries. Hon. J. D. Cox describes multiplication by fission in *Stentor mulleri*. An article on Primitive man follows, after which Mr. A. S. Packard, jun., describes and figures the Cave-beetles of Kentucky. Prof. Farlow writes on University Instruction in Botany. General Notes and a few short reviews follow, the number being completed by notes and notices of meetings.

Zeitschrift der Oesterreichischen Gesellschaft fur Meteorologie, March 1.—This number contains a long article on the relations of temperature and moisture in the lowest atmospheric strata during the formation of dew, by Dr. R. Rubenson, of Stockholm. Observations made by Dr. Hamberg, at Upsala, on temperature at different heights on frosty nights led him to conclude that in the lower strata temperature increases with height, and that the

absolute moisture is less on the ground than a few feet above it. The chief results obtained by Dr. Rubenson during the summer of 1871, by a method of observation differing from that of Dr. Hamberg, may be summed up as follows:—Before the fall of dew the absolute moisture continues to increase and is greatest on the ground, diminishing with height. As soon as dew begins to fall, moisture decreases on the surface of the ground, and this decrease keeps pace with the decrease of temperature. The decrease of moisture extends upwards rather rapidly, and can be detected at four feet just after the first deposition of dew. On the ground the decrease per hour amounts to a maximum of about 0·73 mm., while half a foot above it the decrease only reaches 0·65 mm., which is less than one corresponding to the lowering of temperature. The higher the instrument the later does the decrease of moisture show itself, and the less the change per hour. It appears that owing to a fall of temperature on the ground, the air immediately above it becomes saturated, dew falls, and temperature and moisture diminish. At a certain point, owing either to diffusion or a descending current, fresh vapour supplies the place of that condensed as dew, and part of the loss of each stratum is successively made up by the moister stratum above it, but not the whole, for the diminution continues in all the strata. Time being required for the propagation of the decrease upwards, the lowest stratum loses more of its moisture than any of the strata above it.

Zeitschrift für Wissenschaftliche Zoologie, 1875. 2nd Supplement.—This part contains a memoir by Oscar Schmidt, on the embryology of calcareous sponges, in which Haeckel's observations and conclusions are attacked, and his Gastræa theory is destroyed, as far as calcareous sponges are concerned. Unfortunately, at a critical point Oscar Schmidt failed to follow his embryos, and the real purport of his observations remained uncertain until the publication of Schulze's researches hereafter mentioned.—Dr. William Marshall contributes a long memoir on the hexactinellid sponges, figuring and describing new species, with their characteristic spicula. His most interesting new form is one in which the central cavities of the spicula coalescing to form the meshes of the skeleton become perfectly continuous by their protoplasmic contents.

The 3rd Supplement (1875) commences with F. E. Schulze's memoir above referred to, on the structure and development of *Sycandra raphanus*. His beautiful figures give the various stages of segmentation, and the arrangement of the segmentation spheres into groups of different sizes, one set of these giving rise to the invagination by which the Gastrula form is constituted. This sponge is now accepted by Haeckel as exemplifying his Amphiblastic type, while other calcareous sponges form archiblastic embryos, in which the segmentation spheres remain similar to one another until after the Gastrula is formed.—August Weissmann contributes a philosophical paper on the transformation of the Axolotl into Amblystomas. He believes that this transformation is to be regarded as a retrogression, and that the present Axolotl represents a former Amblystoma whose structure has been modified by changed conditions of life.—Prof. Nitsche continues his valuable memoirs on the Bryozoa, the present instalment being devoted to the process of gemmation. He shows that all the structures in the new zooid are produced from the ectoderm of the parent, and insists on the important morphological consequences of this fact, while deprecating the precise schemes of embryogeny and phylogeny now so much in vogue.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, May 11.—On Simultaneous Barometric Variations in India, by J. A. Broun, F.R.S.—After Pascal showed that the mercury in the barometer tube stands lower at the top than at the foot of a mountain because the mass of air above the barometer is less in the former than in the latter case, it was a natural conclusion that the variations in the height of the mercury observed with a stationary barometer are due to the same cause. Various hypotheses have been proposed to explain how the aërial mass is increased or diminished, none of which, however, can satisfy the facts now known, being either insufficient or untrue. The author, after referring to the latest of these hypotheses, gives results which he has deduced from observations made at three stations in India; namely, at Simla, 7,000 feet above the level of the sea, on a spur of the Himalayas, at Madras, and at Singapore, near the sea-level, the last being 2,700 miles from the first, and 1,800 miles from the second station.

When the daily mean height of the barometer is taken, a large movement is found occupying nearly twenty-six days, a movement attributed by the author to the sun's rotation on his axis; but it is the smaller oscillations of the daily mean atmospheric pressure, the secondary maxima and minima, which are especially examined. The present discussion has been limited to three months, during which there were eighteen of these maxima and minima. The author finds that the mean interval between the times of maximum pressure at any two stations is less than seventeen hours, and between the times of minimum pressure less than ten hours. In four out of eight cases of minima the lowest pressure was attained at all the three stations within six hours. The results of these comparisons is shown to extend even to St. Helena.

It was pointed out that though in general maxima and minima happened at the three stations near the same hour, there were one or two marked exceptions to the rule; one of these, a fall in the height of the mercury of three-tenths of an inch within thirty-six hours, at Simla, was not perceived at any of the other stations. This, the greatest of all the disturbances of atmospheric equilibrium during the period examined, was shown to be connected with a great thunderstorm at Simla (not felt at the other places), and was thus due to a local cause, while the other variations, some of about one-thirtieth the amount of that just mentioned, happened nearly simultaneously over an area of at least a million square miles.

The author suggests that another cause is required to explain these facts than variations of mass through thermic or other actions, the whole climatic conditions being different at the various stations; in other words, *that the attraction of gravitation is not the only attractive force concerned in the variations of atmospheric pressure.*

Linnean Society, May 24.—Annual General Meeting.—Prof. Allman, F.R.S., president, in the chair.—There were presented by Mrs. J. J. Bennett, and a vote of thanks accorded, three medals, memorials of Linnæus—one of silver, struck in 1746, given by Linnæus to Haller in exchange for his portrait; one of gold, dated 1747, struck at the expense of Count Tessin; and a large silver one, designed by Lynberger, struck by command of the King of Sweden in commemoration of the death of Linnæus, Jan. 10, 1778.—Mr. J. Gwyn Jeffreys, treasurer, read his statement of the accounts, &c., of the Society for the year 1875. These showed its financial position to be very favourable, and, indeed, prosperous. The increase in the number of Fellows was very marked, and everything augured the Society's retaining their well-earned reputation and usefulness as a scientific body.—The President then delivered his anniversary address, choosing as a topic the department of biology, treating of those remarkable forms, the border-land between vegetable and animal life. He began by allusion to De Bary's researches on Myxomycetes and its curious transformations; then referred in detail to Cienkowski's remarkable observations on Vampyrella and the marine sarcodous organisms, Labyrinthulæ. Dr. Archer's Chlamydomyxa, Haeckel's Myxastrum, and Magosphaerica, were each passed in review, and a comparison of all these forms entered into, with their peculiar phases and relations to each other. He observed that in them protoplasm was reduced to its simplest nature, evincing what might be considered vegetative or animal life, according to stage, &c. He summed up by regarding life as a property of protoplasm, but very different from conscience and will, or indeed any of the psychological phenomena. The following Fellows were elected into the Council:—J. G. Baker, Dr. W. P. Carpenter, Henry Lee, Prof. W. K. Parker, and S. J. A. Salter, M.B., in the room of the subjoined, who retired: W. T. T. Dyer, J. E. Harting, W. P. Hiern, M.B., Dr. J. D. Hooker, C.B., and J. J. Weir.

Chemical Society, May 18.—Prof. Abel, F.R.S., president, in the chair.—A paper on hemine hematine and a phosphorised substance contained in blood corpuscles, by Dr. J. L. Thudichum and Mr. C. T. Kingzett, was read by the latter.—Prof. W. N. Hartley then made a communication on the natural carbon dioxide from various sources, being a continuation and extension of his former paper on the presence of liquid carbonic anhydride in the cavities of quartz and other minerals.—Mr Kingzett subsequently read a note on some trials of Frankland and Armstrong's combustion process *in vacuo*, by Dr. Thudichum and himself.—Mr. T. Fairley gave a short account of three papers on

peroxides, in which he described various reactions with hydrogen peroxide, and also the preparation of sodium and uranium peroxides, on chromic and perchromic acids, and on the estimation of nitrogen.—The Secretary read a paper, by Prof. J. W. Mallet, on aluminium nitride and the action of aluminium on sodium carbonate at a high temperature. The nitride forms small crystalline particles of a yellow colour.—Lastly, Mr. E. Neison gave a short account of a process for the estimation of mercury.

Royal Astronomical Society, May 12.—Mr. W. Huggins, president, in the chair.—The Rev. Frederick Howlett presented to the Society five volumes of sunspot drawings made between the years 1859 and 1874. They contain several drawings of sunspots on a large scale, some of which have already been figured in the pages of the *Monthly Notices*, and other places. A letter was read from Mr. Birmingham informing the Society that Dr. Schmidt's great lunar map of six French feet diameter will soon be issued by the Prussian Government. It has been the labour of thirty-four years, and contains 34,000 craters besides rills and other objects.—A paper by Mr. Dunkin was read on the conjunction of Venus with λ Geminorum, on August 18, 1876, when there will be an excellent opportunity for making micrometrical measures of the planet's parallax with respect to the star. Its nearest approach will be seen from stations in North and South America a little before sunrise.—A paper by Mr. Hind was read on the transit of the great comet of 1819 across the sun's disc. The transit happened on its approach to perihelion, and the comet was not observed until some days afterwards, when it was receding from the sun. After a few weeks Olbers calculated the elements of its orbit, and announced the fact that on the previous 26th of June it must have passed at its ascending node between the earth and sun. Some five years afterwards Pastorff wrote to the Baron de Zach to inform him that he had seen the comet upon the sun's disc, and had, upon the day of its transit, made a drawing of it and a measure of its distance from the sun's limb. He describes it as a nebulous body 6′ in diameter with a bright centre. His original drawing is preserved in the library of the Astronomical Society. Mr. Hind has carefully recalculated the elements of the comet's orbit, and has found that at the time mentioned by Pastorff the comet must have appeared much nearer to the sun's centre than the position indicated by Pastorff. Canon Stark of Augsburg, also published an account of a nebulous body seen upon the sun's disc at 7h. 5m. on the morning of June 26. The measures given by him of the position of the black spot do not agree with the position calculated by Mr. Hind, although there is less discrepancy between them and the calculated position than there is in the case of Pastorff's observation. Mr. Hind is disposed to think that neither Stark's nor Pastorff's observations are to be depended upon.—Mr. Christie read a note on the displacement of lines in the spectra of stars, from which it appeared that the discrepancies between the results of his observations and those of Mr. Huggins only amounted in the case of most of the stars which had been given by him to some three or four miles per second. The meeting adjourned till June 9.

Geological Society, May 24.—Prof. P. Martin Duncan, F.R.S., president, in the chair.—The following communications were read:—"On the old glaciers of the northern slope of the Swiss Alps," by Prof. Alphonse Favre. The author said that in existing glaciers two parts may be recognised,—an upper one, the reservoir or feeding glacier, and a lower one, the flowing glacier. Applying this division to the old glaciers, it appears that in the glaciers of the Rhone and Rhine the flowing glacier which occupied the plain had a surface nearly equal to that of the feeding glacier which was situated in the mountains. He showed (1) that the Rhone glacier passed over several of the chains of the Jura, and that the ice covering these, far from being an obstacle to the extension of the glaciers of the Alps, actually reinforced them, and served them as *relays*, the glaciers of the Jura having carried far on the Alpine erratic blocks; (2) that the slopes of the upper surface were variable, and were null, or nearly so, over considerable spaces. During their greatest extension the Swiss glaciers came in contact with those of central France near Lyons; they united with those of the Jura, the Black Forest, and the Austrian and Italian Alps; they stretched from the plain of the Po to that of the Danube; and further, for distances of 50 or 100 kilometres they nearly approached horizontality. Hence they resembled the glaciers of the interior of Greenland and Spitzbergen, so far as can be judged from the descriptions.—Evidences of Theriodonts in Permian deposits elsewhere than in South Africa, by Prof. R. Owen, F.R.S. In this paper the author noticed some described reptilia which he believes to belong to his order Theriodontia. The genus *Eurosaurus* was founded in 1842 by Fischer von Waldheim upon some fragments of bone, including a humerus with a broad proximal end as in Kutorga's *Orthopus*; and Fischer also noticed a humerus showing characters like those of Kutorga's *Brithopus*, from the same locality as the portion of a jaw described under the name of *Rhopalodon Wangenheimii*, Fischer. In 1858, H. von Meyer described a skull from the Permian of the Oural, under the name of *Mecosaurus uraliensis*, as a Labyrinthodont; and Eichwald referred this genus, with Kutorga's *Brithopus* and *Orthopus*, to Fischer's *Eurosaurus*. The author regarded *Mecosaurus* as truly Labyrinthodont; whilst the Permian forms constituting Kutorga's genus were referred to the Theriodont order. From the same locality as the above Kutorga describes *Syodon biarmicum* as probably a Pachyderm. Its teeth resemble those of *Cynodraco*. Eichwald's *Deuterosaurus biarmicus* is founded upon the fore part of both upper and lower jaws of a reptile, containing teeth with denticulate or crenulate trenchant borders, the canines being large, especially in the upper jaw. *Deuterosaurus* closely resembles *Cynodraco*, and still more the *Lycosaurus* of the Karoo beds of the Sneewberg range. All the above are from the Permian beds of the Oural, and the author regards them as furnishing important evidence of the Palæozoic age of the Karoo series, in which the Theriodont reptiles are best represented. The author further noticed a Theriodont allied to *Lycosaurus* from a red sandstone, probably of Permian age, in Prince Edward Island. The remains include the left maxillary, premaxillary, and nasal bones; the teeth, implanted in distinct sockets, have sub-compressed, re-curved, conical, pointed crowns, with minutely crenulated borders. This fossil has been described by Dr. Leidy under the name of *Bathygnathus borealis*. Thus, supposing the affinities of the fossils from the Oural and Prince Edward Island to be correctly determined, the reptilia distinguished by mammalian characters are shown to have had a very wide range. Further, the author thinks that the Theriodont reptiles of the Bristol Dolomitic conglomerate may also prove to constitute a family in the Theriodontic order.

Physical Society, May 27.—Prof. Gladstone, vice-president, in the chair.—The following candidates were elected members of the Society:—Herbert Taylor, Rogers Field, and Channell Law.—Mr. W. Ackroyd read a paper on selective absorption. Two typical experiments were shown upon which a division of selective absorption may be based. In the first, light is transmitted through bichromate of potash at the normal temperature and again at about 200° C.; and the spectrum of the transmitted light is examined. The widening of the absorption-bands which takes place at the higher temperature is traced to structural alterations. In the second experiment light is sent through two thicknesses of the same coloured solution, as, for example, sulphate of copper, and in the greater thickness the absorption-band has widened out, but this is plainly not owing to any structural alteration. That in the first experiment he proposes to term *structural*, and that in the second *transverse* absorption, and he considers that these two kinds have not hitherto been sufficiently distinguished. Certain colour relations which exist among anhydrous binary compounds led the author to the conclusion that the width of a structural absorption-band bears a direct relation to interatomic distance. The necessity for separating high temperature spectra from low was shown, and the bearing of the subject on the study of organic colouring matters briefly alluded to.—The Secretary then read a communication from the Rev. R. Abbay, on certain remarkable atmospheric phenomena in Ceylon. The most striking of these is witnessed from the summit of Adam's Peak, which is a mountain rising extremely abruptly from the low country to an elevation of 7,200 feet above the sea. The phenomenon referred to is seen at sunrise, and consists *apparently* of an elongated shadow of the mountain projecting westward to a distance of about seventy miles. As the sun rises higher it rapidly approaches the mountain and appears at the same time to rise before the observer in the form of a gigantic pyramid of shadow. Distant objects may be seen through it, so that it is not really a shadow on the land, but a veil of darkness between the peak and the low country. It continues to rapidly approach and rise until it seems to fall back upon the observer, like a ladder which has been reared beyond the vertical, and the next instant it is gone. Mr. Abbay suggests the following explanation of the phenomenon:—The average temperature at night in the low country during the

dry season is between 70° and 80° F. and that at the summit of the peak is 30° or 40° F.; consequently the low strata of air are much the less dense, and an almost horizontal ray of light passing over the summit must be refracted upwards and suffer total internal reflexion, as in ordinary mirage. On this supposition the veil must become more and more vertical, as the rays fall less horizontally, and this will continue until they reach the critical angle, when total internal reflexion ceases and it suddenly disappears. Its apparent tilting over on the spectator is probably an illusion, produced by the rapid approach and the rising of the dark veil without any gradual disappearance which can be watched and estimated. It will be evident that the illumination of the innumerable particles floating in the atmosphere causes the aerial shadow to be visible by contrast. Another interesting phenomenon visible in the mountain districts admits of an equally simple explanation. At times broad beams apparently of bluish light may be seen extending from the zenith downwards, converging as they approach the horizon. The spaces between them have the ordinary illumination of the rest of the sky. If we suppose, as is frequently the case, that the lower strata of air are *colder* than the upper, the reflexion spoken of in the case of Adam's Peak will be downwards instead of upwards. If several isolated masses of clouds partially obscure the sun, we may have several corresponding inverted veils of darkness like blue rays in the sky all apparently converging towards the same point below the horizon. This latter phenomenon is called by the natives "Buddha's Rays."—Prof. Dr. Forel of Morges, Switzerland, then gave, in French, an account of some interesting observations which he has recently made on the periodic waves which take place on the Swiss lakes and are there called "Seiches." It was long since observed that the waters of most of these lakes are subject to a more or less regular rise and fall, which at times have been found to be as much as one or two metres. M. Forel has studied this phenomenon in nine different lakes, and finds that it varies with the length and depth of the lake and that the waves are in every way analogous to those already studied by Prof. Guthrie in artificial troughs, and follow the laws which he has deduced from his experiments. Most of the observations in Switzerland were made on the lake of Geneva, but that of Neuchâtel was found to be best fitted for the study of the subject, possessing as it does an extremely regular geometric form. The apparatus he employed was very sensitive to the motion of the water, being capable of registering the waves caused by a steamboat half an hour after it had passed, and five minutes before its arrival, and was so constructed as to eliminate the effect of common waves, and to register the motion side by side with a record of the state of the barometer, on paper kept in continuous motion. While he found the duration of waves to be ten minutes at Morges it was seventy minutes at Geneva, and this is explained by the narrowness of the neck of the lake at the latter place. This period he proved to be independent of the amplitude, and to be least in the shortest lakes. For shallow lakes the period is lengthened and his observations show that the period is a function of the length and depth and that longitudinal and transverse waves may coexist, just as Prof. Guthrie has shown to be the case in troughs.

Stockholm

Academy of Sciences, March 12.—Herr Rubenson communicated a paper entitled "Monthly and yearly averages of Temperature at the State Meteorological Stations during the Years 1859-1872."—Herr Smitt gave an account of a visit paid by Herr P. Olsson, assisted by a grant from the Academy, to Norrland for zoological research.—Herr Th. M. Fries gave an account of two reports made to the Academy—one by Docent Berggren, who had gone to New Zealand for the purpose of studying its flora, and the other by Dr. Hellbom, who had made a lichenological visit to Norrland.—The following papers were communicated:—On the influence of inequalities with long period on the expression for the absolute perturbations of periodic comets, by Herr Gyldén.—Narrative of an expedition to Novaya Zemlya and the mouth of the Jenesei in 1875, with map, by Prof. Nordenskjöld.—On the simultaneous covariants of the fourth order and fourth class of two conic sections, by Prof. Bjorling.—On sulphonaphtholid, by Prof. Cleve.—On the action of pentachloride of phosphorus on β naphthol, by Prof. Cleve and Candidate Julin-Dannfelt.—On the estimation of nickel in nickeliferous magnetic pyrites, by Herr Ekelund.—Contributions to the knowledge of the development of Rajæ, by Intendent Malm.—Contributions to the Orthopter-fauna of South Africa, by Prof. Stål.

Paris

Academy of Sciences, May 29.—Vice-Admiral Paris in the chair.—The following papers were read:—On the atomic constitution of bodies, by M. de Saint-Venant. There is nothing contradictory in regarding atoms as material points having all the properties of visible and tangible bodies, less extension.—New remarks on the real existence of a matter formed of isolated atoms comparable to material points, by M. Berthelot. He gives reasons for withholding assent to MM. Kundt and Warburg's view.—On the salts formed by peroxide of manganese, by M. Frémy.—Observations on a basking shark recently caught at Concarneau, by MM. Gervais. This species (*Squalus maximus*) is found but rarely in temperate waters. It has a number of flexible, elastic filaments (of osseous nature) attached to the branchiæ; these sift the water, retaining the small animals as food.—Examination of the possible mechanical action of light. Study of the radioscope of Mr. Crookes, by M. Ledieu. The author's theory (implying a special action of polarised light) was submitted to the test of experiment by M. Fizeau, but with negative results. Further experiments are promised.—The Caucasus and its mineral waters, by M. François.—Intensity of gravity in the island of St. Paul, by M. Cazin. The apparent acceleration of gravity there exceeds the theoretical acceleration by $\frac{1}{1000}$ of its value. May not this affect astronomical observations?—On the radiometer of Mr. Crookes, by M. de Fonvielle. He describes experiments, whence he infers an impulsive action of light. M. Fizeau says that if a bundle of solar rays fall on the instrument, limited by a screen so that they strike only the polished surfaces, the rotation is such that each vane comes to meet the rays instead of escaping from them, as would be the case if the light had impulsive force.—On the Phylloxeras of the leaves of the French vine, by M. Delachanal.—On the laws of matter, by M. de Marsilly.—On a compressed air filter for water, by MM. Chanoit and Midoz.—On the transformation of elliptic functions, by M. Laguerre.—On the development in series of the functions Al(x), by M. Joubert.—On the charge taken by the disc of the electrophorus, by M. Douliot. He describes an arrangement by which he verified the theoretical conclusion that the charge of the disc is proportioned to its radius.—Theory of spectra; observations on Mr. Lockyer's last communication, by M. Lecoq de Boisbaudran. All spectral lines change in relative intensity when the temperature is raised; Mr. Lockyer's theory would imply that each element is decomposed into as many more simple substances as its spectrum has lines. Considering the immense number of lines in certain spectra, such a view seems little probable.—On the constitution of prophylenic monochlorhydrines, and the law of addition of hypochlorous acid, by M. Henry.—On a quinoacetate of calcium, by M. Gundelach.—Variations of the electric state of the muscles in voluntary contraction and artificial tetanus, studied with the aid of the galvanoscopic limb, by MM. Morat and Toussaint.—Anaesthesia by the method of intravenous injections of chloral; amputation of the thigh; absolute insensibility; consecutive sleep for six hours; cure without any accident; by M. Oré.—On frauds met with in the points of lightning conductors, by M. Francisque Michel.

WALLACE'S GEOGRAPHICAL DISTRIBUTION OF ANIMALS

The Geographical Distribution of Animals, with a Study of the Living and Extinct Faunas, as Elucidating the Past Changes of the Earth's Surface. By Alfred Russel Wallace. Two Vols. 8vo. (London: Macmillan and Co., 1876.)

THE question of the number and boundaries of the primary zoological regions of the Globe has recently been discussed by Prof. Newton in his article on "Birds," in the new edition of the "Encyclopædia Britannica." After remarks on the failure of previous writers to solve this problem in a satisfactory manner, Prof. Newton comes to the conclusion that the outlines of distribution laid down in 1857 by Mr. Sclater, although founded only upon the study of the erratic class of birds, have "not merely in the main, but to a very great extent in detail, met with the approval of nearly all those zoologists who have since studied the subject in its bearing upon the particular classes in the knowledge of which they themselves stand pre-eminent." In point of fact, Mr. Wallace himself was one of the first naturalists to accept Mr. Sclater's views on this subject. Writing from the remote island of Batchian, in the Indian Archipelago, in March 1859, after perusing Mr. Sclater's well-known memoir on the Geographical Distribution of Birds,[1] Mr. Wallace says, in a letter to Mr. Sclater published in the first volume of the *Ibis*,[2] "With your division of the earth into six grand zoological provinces I perfectly agree, and I believe they will be confirmed by every other department of zoology as well as by botany." In the two excellent volumes now before us, in which are embodied the results of several years continuous labour upon this and kindred branches of the same subject, it will be seen that Mr. Wallace has not altered his opinion. The six great primary zoological regions of the Globe proposed by Mr. Sclater in 1857 are fully adopted, and form the basis of Mr. Wallace's whole treatment of the subject. But one slight change even in their nomenclature is made—that of substituting "Oriental" as the name of the Region embracing South Asia and the adjacent islands for Mr. Sclater's term "Indian." In fact, after discussing the general principles and phenomena of distribution and what little we as yet know concerning the distribution of extinct animals, the main portion of Mr. Wallace's volumes is occupied by an elaborate sermon on Mr. Sclater's text, and on its application to other classes of animals. The various phenomena of life exhibited in the Palæarctic, Ethiopian, Oriental, Australian, Neotropical, and Nearctic regions are treated of in succession, and their similarities and their differences are discussed. To this is added a sketch of the geographical distribution of the principal families of terrestrial animals arranged systematically, which forms the fourth part of this important work. Of this last portion, which is, in fact, a book of reference containing an account of the distribution of all the families, and of most of the genera of the higher animals arranged in systematic order, we propose to speak in a subsequent article. For the present we will confine our attention to the first three parts of Mr. Wallace's work.

The introductory chapter, with which the first volume of the "Geographical Distribution of Animals" is commenced, although it states the object of the work plainly enough to the mind of the scientific reader, seems a little too brief and concise to explain the nature of the problem under discussion to the general public. It must be borne in mind that the very idea of the existence of any regular laws of distribution is a novelty to most people—even, we regret to say, to many who call themselves naturalists. It is to be regretted, therefore, we think, that Mr. Wallace has not devoted a few more pages to the general explanation of the subject of which he treats, to the pointing out of the many subordinate problems which it involves, and in particular to the further explanation and definition of such technical terms as "*habitat*," "stations," "range," and "representative species," which confront us in some of the very first pages of his work.

In his second chapter Mr. Wallace discusses the means by which animals are dispersed, and devotes a good deal of space to the question of migration. Now, migration is, no doubt a very important phenomenon, but whether it has much to do with the general theory of distribution appears to be rather doubtful. It occurs only in one or two groups of animals; and, as Mr. Wallace himself observes, "we must, except in special cases, consider the true range of a species to comprise all the area which it occupies regularly for any part of the year." Migration, therefore, primarily affects the distribution of a species within its own specific area, and only has to do with the general question of distribution so far as it may increase the tendency of a species to vary its range. With Mr. Wallace's views on the subject of dispersal generally we cordially agree. There can be no question that, in the "glacial epoch" and in the more recent geological changes which have taken place on the earth's surface, the key of the present complicated phenomena of distribution should be sought, although many of them have had a much earlier origin. "Almost every mile of land-surface has been again and again depressed beneath the ocean; most of the great mountain chains have either originated or greatly increased in height during the Tertiary period; marvellous alterations of climate and vegetation have taken place over half the land-surface of the earth; and all these vast changes have influenced a globe so cut up by seas and oceans, by deserts and snow-clad mountains, that in many of its more isolated land-masses, ancient forms of life have been preserved, which, in the more extensive and more varied continents have long given way to higher types."

Mr. Wallace now proceeds to enter upon the grand question of Zoological Regions, entirely ignored, as he truly says, by the older school of naturalists. To them, provided they got the object, it little mattered whence it came. "The Brazils," the "East Indies," or the "South-sea Islands," was considered *ample* information as to the locality of any specimen, even if it were thought necessary to give such information at all. How could such men appreciate the idea of Zoological Regions? They

[1] See "Journal of the Proceedings of the Linnean Society," Zoology, ii. p. 130.

[2] Letter from Mr. Wallace concerning the Geographical Distribution of Birds. (*Ibis*, 1859, pp. 449.)

had a sort of vague notion that certain forms were peculiar to hot climates, and that certain others were only found in cold countries, but that was about all they knew or cared to know. Of the necessity of precise knowledge on the subject of locality they were absolutely incredulous.

"To the modern naturalist, on the other and," as Mr. Wallace most truly observes, "the native country (or 'habitat' as it is technically termed) of an animal, or a group of animals, is a matter of the first importance; and as regards the general history of life upon the globe, may be considered to be one of its essential characters. The structure, affinities, and habits of a species, now form only a part of its natural history.

"We require also to know its exact range at the present day and in prehistoric times, and to have some

FIG. 1.—Forest in Borneo.

knowledge of its geological age, the place of its earliest appearance on the globe, and of the various extinct forms most nearly allied to it. To those who accept the theory of development as worked out by Mr. Darwin, and the views as to the general permanence and immense antiquity of the great continents and oceans so ably developed by Sir Charles Lyell, it ceases to be a matter of surprise that the tropics of Africa, Asia, and America should differ in their productions, but rather that they should have anything in common. Their similarity, not their diversity, is the fact that most frequently puzzles us."

Yet, in spite of the increased attention paid to locality by Swainson, Waterhouse, Strickland and all the more

highly educated class of naturalists within the last fifty years, it was not until 1857 that the plan of determining the great zoological regions of the earth's surface not from *à priori* reasons of heat and cold, nor from the ordinary views of geographers, but by the minute study of the actual ranges of the more important and best known groups of animals was suggested. Mr. Sclater's Regions, then originally established from consideration of the ranges of the principal families and genera of birds, were quickly applied by Dr. Günther to reptiles and batrachians, and subsequently by Mr. Sclater himself to mammals. Working from the same stand-point, various naturalists have of late years tried to improve upon them, amongst others Mr. Blanford, Mr. Blyth, and

FIG. 2.—Scene in New Guinea.

Prof. Huxley. Mr. Wallace will have none of these—nay, so convinced is he of the correctness of Mr. Sclater's original "happy thoughts"—that he will not even listen to the inventor's own emendations of his original regions. "So that we do not violate any clear affinities"—he observes, "or produce any glaring irregularities, it is a positive, and by no means an unimportant advantage to have our named regions approximately equal in size, and with easily defined and easily remembered boundaries."

He therefore condemns "all elaborate definitions of inter-penetrating frontiers" and "regions extending over three-fourths of the land-surface of the globe" as "most inconvenient—even if there were not such differences of opinion about them." He admits that the "most radical

zoological division of the earth" is made by "separating the Australian regions from the rest," and that the best natural division of the remainder is effected by cutting off the Neotropical region. We should then have three primary zoological regions, which first Prof. Huxley, and afterwards Mr. Sclater, in his oral lectures on geographical distribution seemed to consider as of nearly equal importance. On this Mr. Wallace remarks that "in isolation and speciality, determined by what they want, as well as by what they possess, the Australian and Neotropical regions are undoubtedly each comparable with the rest of the earth. But in richness and variety of forms they are both very much inferior, and are much more nearly comparable with the separate regions which compose it." After discussing this subject at some length, and disposing shortly of Mr. Allen's system of "circumpolar zones," Mr. Wallace comes to the conclusion that a consideration of all the facts zoological and palæontological, indicates that the great northern division, or *Arctogæa*, is as much more important than either Australia or South America, as its four component parts are less important. He therefore reverts to the six original regions proposed by Mr. Sclater in 1857, as the most workable, and most conveniently adapted for the study of zoological distribution.

Thus much having been settled, Mr. Wallace proceeds to point out the limits of the six great regions, and to indicate the sub-regions into which they may be best divided. As regards the latter part of this task there is much difficulty. It must be confessed that the sub-regions in many cases are as yet only approximately determined, and that those adopted by Mr. Wallace are in several instances open to serious question. For example, "the great central mass of South America, from Venezuela to Paraguay" is constituted in the present work as a single division of the Neotropical region under the name of the "Brazilian Sub-region." But there can be no doubt that within this area there are two, if not three, distinct sub-regions which deserve recognition. The fauna of south-eastern Brazil, so admirably investigated by Prince Max. of Neuweid, Burmeister, Reinhardt, and other well-known naturalists, is very distinct from that of the great Amazonian valley, and the adjacent flats of Guiana and the Orinoco. Many genera are peculiar to each of them, and a whole host of representative species perform similar functions within the respective areas. Herr von Pelzeln's divisions of the Neotropical region, and those employed by Messrs. Sclater and Salvin in their papers published in the Zoological Society's *Proceedings*, are much more natural than those suggested by Mr. Wallace. We fear that in spite of what he says on the subject our author has rather allowed a hankering after uniformity to lead him astray and to induce him to restrict his sub-regions to four in each case.

The chapter on Classification which next follows, and concludes the first portion of the work, contains some very apposite remarks. A natural classification of animals is, as Mr. Wallace observes, of first-rate importance in discussing matters of distribution. But, except in the case of a few groups, we have by no means yet attained to a natural classification of animals, and even as regards these we are, in the opinion of many naturalists, still very [illegible] only therefore some few of the classes of animals that are sufficiently known to be useful for the study of distribution. As such Mr. Wallace selects the Vertebrata, the butterflies, and six families of Coleoptera amongst the insects, and the terrestrial and fresh-water land-shells amongst the Mollusca. Of these better-known groups he gives us tables of the arrangement which he proposes to adopt for the illustration of his remarks on their geographical distribution.

(*To be continued.*)

OUR BOOK SHELF

Notes on Collecting and Preserving Natural History Objects. By J. E. Taylor, E. F. Elwin, Thos. Southwell, Dr. Knaggs, E. C. Rye, J. B. Bridgman, Prof. Ralph Tate, Jas. Britten, Prof. Buckman, Dr. Braithwaite, Worthington G. Smith, Rev. Jas. Crombie, W. H. Grattann. Edited by J. E. Taylor, Ph.D., F.L.S., F.G.S., &c. (London: Hardwicke and Bogue, 1876.)

THIS is a republication of a series of papers from *Science Gossip;* and the names of the respective authors is a sufficient guarantee for the value and accuracy of the information it affords. It is a very useful book to put into the hands of young persons with some taste for natural history but quite ignorant of how to collect and what to observe; since it devotes as much space to the latter branch as to the former, and is thus a more instructive work than its title indicates. The subjects discussed are—geological specimens, bones, birds' eggs, lepidoptera, beetles, hymenoptera, land and fresh-water shells, flowering plants, grasses, mosses, fungi, lichens, and seaweeds. It is a pity that a few other essays were not obtained—on birds, mammals, reptiles, fresh-water fishes, crustacea, spiders, and sea-shells—so as to make the book somewhat more complete as regards "Natural History Objects;" but so far as it goes it is an excellent little work, and is perhaps better adapted to encourage an incipient taste for the study of nature than many more pretentious volumes. The chapters on birds' eggs, butterflies, and beetles, are especially full and interesting; while those on bones and fungi are valuable, as likely to incite the reader to take up the study of these somewhat neglected objects.

The Harris Cubit of Karnak

As the measures of this cubit hitherto published are more or less incomplete, the following series may be worth attention.

For permission to examine this relic, I am indebted to Dr. Birch, under whose care it is placed in the British Museum; and who, with his usual courtesy, gave every facility for its measurement.

The readings were taken by laying this wooden cubit on a brass standard scale, divided to tenths of an inch and to millimetres, with its divided face at right angles to that of the scale. Two observers then read the values of the divisions in both inches and metres, giving four readings in all, at about 66° F. The standard scale has since been kindly verified by Mr. H. W. Chisholm, Warden of the Standards, and its error is not of such an amount as to affect the figures here given; it is now in the Loan Collection of Scientific Apparatus (200), the sole representative at South Kensington of Kater's standards.

The readings were mapped on divided paper, and the mean result for each line carefully estimated, with its probable error, by the two observers: and though the following readings of the divisions are of course far from the limit of attainable accuracy, yet as their errors are but a small fraction of those of the gradua-

tions of the cubit, farther accuracy would be nearly useless, especially in view of the width and deficient symmetry of the dividing lines.

The zero point of the series is adjusted so as to fit the normal scale of equal spaces deduced from it, with equal errors + and —, on the series of palms.

	British Inches. Cubit Divisions.	British Inches. Normal Scale.
End of rod	—·026	·000
Palms	2·952	2·956
	5·911	5·913
	8·873	8·869
	11·820	11·826
	14·779	14·785
	17·735	17·739
	20·702	20·695
	23·665	23·652
	26·605	26·608
	29·582	29·565
	32·516	32·521
	35·481	35·477
Digit	36·195	36·217
Condyle	36·922	36·956
Digit	37·694	37·695
Palm	38·417	38·434
Condyle	39·910	39·912
End of rod	41·402	41·390

The average probable error of these determinations of each line (omitting the ends) is ·0008 inch, so that it may be called 1 on the last place of figures here given.

The total length of the rod is 41·428 with a probable error of ± ·0025. Sir Gardner Wilkinson (and Queipo from him?) states it as 41·30; John Taylor, 41·46; and Col. Sir Henry James, 41·398. Thus the above determination falls between these three authorities, and is in fact about reached by the probable error of the mean of them.

Besides the total length of the rod, the divisions must be considered as giving a value for the cubit. Leaving, therefore, for separate consideration the lesser subdivisions and ends, we will look only to the series of palms. As these were probably copied mechanically from another standard, and were apparently not produced by stepping lengths on the rod, we should ascertain the mean value they give for a Normal scale, and their errors from it. This carefully computed from these palm divisions is 41·390 for the cubit, or 2·956 for each palm; and the average error of the palm divisions is ·007 (the maximum error is ·018), so the probable error of this value for the mean cubit is about ·002. This average error of $\frac{1}{140}$ inch is rather large, but not worse than would probably be made at the present time in such work. By having a standard scale for comparison, hand dividing may be done on a still longer rod with a quarter of the error of this cubit, or even less; but as a mason's measure, this cubit is at least as accurate as modern examples.

The digit divisions are remarkable; the two last fit the Normal scale as accurately as the palms, but in making the divisions 36·195 and 36·922, the scale has apparently slipped away from that end of the rod about ·028; and thus these have an average — error of that amount. The ends appear to have been left rather long, perhaps to allow for wear, being ·026 and ·011 too long respectively, giving an average surplus of ·019. This may be intentional, or may result from being copied from a longer standard than the subdivided prototype, or may be merely an error. In any case, the tolerable equality of the surplus at each end, seems to show that the subdividing was from another standard, and not by stepping successive distances, as the difference is only $\frac{1}{3000}$ of the total length.

In Queipo's Metrology the value of each palm of this example of the cubit is stated to the millionth of a metre, two places farther than really measured, as they are merely reduced from English inches and hundredths, with an occasional half-hundredth. These values are all about $\frac{1}{300}$ too short (their sum being 41·3, as Sir Gardner Wilkinson's statement), but otherwise they agree closely with the series given above; and their mean difference from it (when corrected for their general shortness) is ·011, or but little more than the hundredth of an inch to which they were originally read.

If from the other eight or nine examples of the Karnak cubit the mean cubit was deduced from the subdivisions, and the internal errors of it thus obtained, we should have more knowledge of the accuracy of the earliest known civilisation, a datum of much interest from a scientific and historical point of view. A similar examination of the measures of classical and mediæval times, including our ancient national standards of all kinds, would also give an idea of the accuracy which in various ages, and for various purposes, has been considered to be the utmost requisite; a maximum datum very different to that obtainable from other remains, which only show the amount of accuracy usually employed. As a chapter of the history of science, now so much considered, this subject should not be longer neglected.

Bromley, Kent W. M. FLINDERS PETRIE

The Chemical Society

THE article which appears in NATURE, vol. xiv. p. 125, on the Organisation of the Profession of Chemistry throws doubt on the expediency of effecting the proposed organisation through the instrumentality of a society which has solely occupied itself with the extension and diffusion of knowledge, viz., the Chemical Society. It farther proposes that as it would be a wide departure from the functions which the Chemical Society has hitherto performed to undertake the appointment of a Board of Examiners, the Universities of Oxford, Cambridge, and London should be asked to co-operate in the matter, being already formed examining bodies, which would probably command and deserve greater confidence than a board nominated by a newly formed Institute, or even by the Chemical Society.

On these remarks I beg to offer the following comments:—

1. The Chemical Society never has promoted the acquisition of such knowledge and skill as are necessary for the discharge of such duties as a professional chemist is required to undertake.

2. If the Chemical Society has performed all other functions but this—the fact is no argument against it appointing a Board of Examiners, or of conferring some distinction on those who are capable of acting in the service of the public as chemists; indeed, if this may conduce to the "general advancement of chemical science," the Society, by not taking such steps, is scarcely fulfilling the duties for which it was originally founded, and by opposing any such scheme it may actually retard the progress of chemistry in this country.

3. The writer of the article is apparently unaware of the fact that it would be very difficult to make any examination answer the purpose of testing a man's skill and technical as well as scientific knowledge in a satisfactory manner. An organisation scheme has been designed by a few gentlemen in conjunction with myself, so as to obviate examination as far as possible, or, in other words, to extend the examination over a period of six years. Those of us who are teachers in medical schools, and particularly those who at times have had to take to "coaching" for a livelihood, see the defects of a system which entirely depends upon examination as a test of qualification. Certainly no University examination would have the confidence of professional chemists. There are many business details besides granting certificates of competency which an organisation of chemists would be obliged to undertake, as, for instance, imposing such observances on the members as would tend to suppress objectionable practices which are somewhat too common at the present time.

The *Chemical News* for June 9 contains a sketch of an organisation scheme, and the conditions of admission for original members are there set forth. If the Chemical Society as a body agrees to accept such a scheme, by all means let it do so, but it does not appear clear whether the qualified Fellows of the Society could constitute a separate body, managing their own affairs, within the Society, without the interference of other Fellows not of the same class.

British chemists are now in request all over the world, Japan, India, China, Canada, and California, and some mark of distinction as "chemists" which those who go abroad might carry with them would be valuable to them and enhance the value of the science in this country. WALTER NOEL HARTLEY

Scientific Club, 7, Saville Row, W.

Lectures on Meteorology

IN these days of the rapid development of the standard sciences, and the multiplication of their offshoots into considerable sections nearly as big as their originators, it may not be inappropriate to represent the claims of meteorology for a separate existence apart from others. As geology and mineralogy have been developed out of the natural history of former times, so it may obviously be suggested that meteorology might be detached from natural philosophy with which it has been

hitherto connected, and be taught as a separate science on its own merits and usefulness, and extent of practical application. It is therefore proposed that meteorology might constitute a separate course of lectures, theoretical and practical, at our colleges, where might be expounded its bearings on navigation, agriculture, human health, and engineering. To it might also be attached the sciences of ventilation of buildings, as barracks, factories, and mines, and hydrology, or a knowledge of ocean and sea currents, and ice drifts.

The foundations for such a professorship in scientific materials have, it is suggested, now reached a sufficient weight and bulk as to furnish ample occupation, and to be of universal interest and general application.

Weather observatories, now numerously established, will require superintendents and assistants, captains of ships would be benefited by some scientific knowledge of the winds and waves, and farmers would find meteorology useful for the successful tillage of the soil.

Again, overseers of mines would derive some good from a knowledge of the mechanism of the currents of the air they have to regulate in ventilation, and engineers of waterworks would require to know the variability and extent of rainfall for the sites and construction of their reservoirs.

Finally, the science of the weather is of most importance of all to those who have to fulfil the duties of health officers in our great towns, and climatology is more than ever studied by the physician having to give advice to the numerous invalids who now travel abroad for the sake of restoration of health by change of air and scene.

In order to facilitate the accomplishment of this object, it is suggested that some means should be taken to originate a fund to defray the expenses of such a course of lectures, either in London or Edinburgh, both of which cities have meteorological societies which might lend their influence to promote such schemes of scientific development.

The class of men to whom resort might be suggested for patronage of this proposition would most likely be shipowners, landowners, and boards of health, either for the study of their self-interest or for the benefit of the public. SPES

Edinburgh, June

THE BRITISH ASSOCIATION—GLASGOW MEETING

THE arrangements for the reception of the British Association are fast progressing towards completion. The Executive Committee met on Tuesday, and the following is a brief sketch of the work which has been done:—

Finance Committee.—The total sum subscribed to the Guarantee Fund amounts to £6,559 10*s.*

Museum Committee.—This Committee has arranged as follows:—The Geological Exhibition will be accommodated in the Corporation Galleries, Zoology and Botany in the lower Queen's Rooms, and Archæology, &c., at the University. These exhibitions will be large and complete, and arrangements have been made for keeping them open, if desired, for some time after the meeting of the Association.

Local Industries Committee.—This Committee has three sub-committees—one for Machinery, one for Chemicals, and one for Textile Fabrics—and the materials for a highly instructive exhibition are being collected, which will be held in Kelvingrove Museum, where there is already a general museum of considerable size and variety.

Reception Committee.—Already a number of distinguished persons have been invited and have accepted invitations. Among these are the President-designate, Prof. Andrews, of Belfast, who will be the guest of Sir William Thomson, the present President, Sir John Hawkshaw, who, with Lieut. Cameron, the African explorer, will be the guest of the Lord Provost. The Duke of Argyll, one of the Vice-Presidents, will be the guest of Prof. Blackburn.

Arrangements have been made with all the leading railway companies in England and Scotland to facilitate the visits of strangers and their stay in Glasgow. A guide and handbook for Glasgow and the West of Scotland is being prepared under the general editorship of Dr. Blackie.

The following places have been secured for the use of the Association:—The University, where, as at present arranged, all the Sections except the Geographical and Ethnological Section (Section E) will meet, Section E meeting in the large upper hall of the Queen's Rooms. At the University, also will be the Reception and Refreshment Rooms. Kelvingrove Museum.—This will be the receptacle for the exhibitions of machinery, of chemicals, and textile fabrics. Queen's Rooms.—Here will be held an exhibition of the zoological and botanical collections of the district, and here also the meetings of Section E will take place. The upper Corporation Galleries will be filled with a geological exhibition, there being no room at the museum at the University to accommodate more than the Archæological Section, in addition to the permanent and temporary exhibits already arranged there. The City Hall and the Botanic Garden Palace have also been secured for the use of the Association. The Chambers of the Association, where all inquiries may be made, will be found at 135, Buchanan Street.

A great many of the citizens have indicated their wish to receive guests, and a list is being drawn up of expected visitors, from which guests may be selected. Notice of its completion will be given by advertisement in the newspapers.

Excursion Committee.—It has been arranged that excursions will take place on Saturday, the 9th, and Thursday, the 14th of September, to the following among other places: Arran, Lochlomond, Loch Fyne, and the Holy Loch, Coatbridge, and Paisley. Mr A. B. Stewart has placed his yacht at the disposal of the Association, as has also Mr. Duncan of Benmore, for dredging expeditions. It is intended that there will be at least one dredging excursion to the Firth of Clyde, or other suitable place. Mr. Duncan will also receive at Benmore a party of 100, who go the round by Loch Fyne, for whom he has arranged a delightful excursion. Mr. Martin of Auchendennan will receive a party at dinner there, and Mr. Campbell of Tullichewan and Mr. Matheson of Cordale have also intimated their desire to show hospitality to members of the Association visiting Dumbartonshire. Mr. Ellis will entertain a party at luncheon at Coatbridge after inspection of the North British Wireworks, and Sir Peter and Mr. Thomas Coates are expected to do the same at Paisley.

ABSTRACT REPORT TO "NATURE" ON EXPERIMENTATION ON ANIMALS FOR THE ADVANCE OF PRACTICAL MEDICINE[1]

II.

Experimentation with the forms of Lycoperdon giganteum, or common Puff-Ball.

IN 1853, while the study of the art of producing safe anæsthesia was fresh upon me, my attention was directed by my friend, Mr. H. Hudson, to the fact that in the country the owners of bees rob the bee-hive of its contents of honey and wax after they have stupefied the bees by driving into the hive the smoke of the common puff-ball—*lycoperdon giganteum.* It struck me at once that I ought to ascertain whether the stupefying agent which is given off in the smoke would act as an anæsthetic on the higher animals and on man, and whether a new and safer anæsthetic than chloroform was contained in it. The results of this research, some of which I published in the *Association Medical Journal* in 1853, showed that the narcotic agent present is indeed a true anæsthetic, and that all animals may be narcotised by it, but that owing to the mode in which it has to be administered, it cannot conveniently be applied to man. All the lower animals about to be subjected to operations of any kind, surgical

[1] Continued from p. 152.

or physiological, could, I found, be rendered insensible by this agent safely and inexpensively. I invented a room or chamber in which animals could be placed so as to be exposed to the anæsthetic, and I introduced the use of this method of anæsthesia. From time to time during the past twenty-five years, many necessary surgical operations have been painlessly performed on domestic animals under this anæsthesia, and almost all my own physiological experiments which would have been painful have been conducted under it without pain. Some other physiologists have followed me in this procedure, and have introduced the puff-ball narcotising box into their laboratories in order to save pain from experiment. In these ways the simple experimental research derived from the observation on the bees has proved doubly useful.

While these researches were first being pursued a friend of mine came to me in great distress because his splendid and favourite retriever dog had been bitten by a rabid dog and was now stricken with rabies. He asked me to destroy his dog in the kennel, as nobody dared to remove the animal. I carried out the request at once by simply closing the door of the kennel, covering it with a horse-cloth, and letting the clarified and condensed fumes from the burning lycoperdon pass into the kennel. The animal lapsed quickly into sleep and died without a struggle. I believe this was the first time in the history of science in which anæsthesia had been employed intentionally and systematically for the painless extinction of the life of the inferior animals. I shall show in a future note the singular importance of this application.

Research with Carbonic Oxide.

The observation that the smoke of the burning lycoperdon would produce anæsthesia in the higher animals led naturally to an inquiry after the agent that was at work in creating the insensibility. I commenced to make an analysis of the smoke in order to determine the question, but was forestalled in discovery by two other experimenters, the late Dr. John Snow,—so well known for his researches in anæsthetics, and as the author of the water theory of cholera,—and by the late Thornton Herepath, one of our most promising young chemists. These two gentlemen almost simultaneously discovered that the gas called carbonic oxide is present in the smoke of the lycoperdon. This was a new light, and led me to study the action of carbonic oxide on animal life. I found that this agent, a colourless and inodorous gas, produced insensibility in precisely the same way as the purified smoke of the puff-ball. I found that when the combustion of the puff-ball was made so perfect that no carbonic oxide was formed, there was no anæsthesia induced by the purified fumes, and so the fact was rendered clear that the special anæsthetic in the smoke is the gas in question. I estimated also the proportions of carbonic oxide that could be breathed in the atmosphere, and the effects of the gas in larger and smaller proportions on the lower animals and on myself.

Experimentation in Relation to Diabetes from Breathing Carbonic Oxide.

In conducting the observations on the action of carbonic oxide on living bodies, I was led to examine the animal secretions, and to my surprise I found that the renal secretion of an animal subjected to the gas yielded evidence of glucose or grape sugar. The fact was of such importance I was compelled to follow it up until I had quite established it, and had proved that by the inhaling of this active gas, a temporary attack of the disease known commonly as diabetes, which in the human subject is often fatal, could always be artificially induced in the dog. In a further experiment I found that the inhalation of common coal-gas diluted with air would produce the same condition, an effect caused by the carbonic oxide which is always present in coal-gas. The same has subsequently been observed in a human subject accidentally exposed to the gas. The ultimate value of these observations has yet to be proved. When I first published, in the *Medical Times and Gazette*, on March 22, 1862, the fact of the artificial production of diabetes by carbonic oxide, nine years after I had first observed it, it was looked upon rather as a curious than a practical demonstration. I have always felt that though it did not seem to offer any immediate practical result, it must some day be useful in throwing light on the origin, or at least on one origin of a fatal malady. Quite recently Dr. Pavy has published some valuable details on the production of diabetes by the same means, that is to say, by making animals inhale carbonic oxide, and he has been able to arrive at some clear ideas on the question of the chemical changes that are involved in the process. We may fully expect to receive from him further valuable information.

I wait a moment at this point to observe that the history of experimental research given in the last note illustrates forcibly the value of what may be called the accidental observations that are picked up in the course of experiment. Who ever would have dreamed that from a practice of stupefying bees in order to rob them of their honey, a practice which has been carried on by the vulgar for many centuries, would come the discovery that the higher animals, and even man himself, can be made to produce glucose, and that they may become afflicted with the symptoms which characterise a destructive disease from a simple perversion in the animal chemistry induced by the smoke of the burning puff-ball ?

Experimentation with Oxygen Gas.

The experiments with carbonic oxide led me to a series of experiments with oxygen gas. The late Sir Benjamin Brodie and Mr. Broughton, in their experiments on this same subject, had observed that when animals are placed in pure oxygen they die, with symptoms of sleep, as if they were narcotized, although the products of respiration are removed. Hence for many years oxygen gas, on which we depend for life, was believed to be a narcotic or sedative poison. In my experiments many new facts came out which modified this view. In the first place I found that some animals, such as frogs, will live in oxygen as readily as in common air ; that herbivorous animals will live in it if it be kept supplied to them in fresh current, but the carnivorous animals will not live in the pure gas for a long time without becoming drowsy and insensible and without undergoing changes of their blood, which are fatal to life owing to separation of the fibrine within the vessels. The most important observation, however, which I made on the subject of the effects of oxygen, is the following :—I found that a narcotic action of the oxygen is produced, however pure from the products of respiration the oxygen is maintained, whenever it is breathed over and over again by being passed backwards and forwards through the chamber in which the animals breathe it. Subjected three times to this passage through the chamber, though it be purified so fully from carbonic acid that it contains less of this gas than the common air, it fails to support the active life of all common animals excepting frogs. In a word, the oxygen assumes a negative condition in which it will not support living function. In a report on these researches, made to the British Association for the Advancement of Science, at the Oxford meeting in 1860, I defined this state as one in which no new poison was produced, but in which the oxygen lost some principle or property by which in its fresh state it sustained the animal life.

The lessons taught by these observations extend to the human family. They show that if the oxygen of the great atmospheric sea in which we all breathe should from any cause assume this negative condition, it will fail to sustain the active life. They explain the depressing effect of breathing over again the same air in close and badly ventilated rooms. They throw a distinct light on that "epidemic condition" of the atmosphere, which, since

the time of Sydenham has been noticed, but never explained, in which diseases of spreading type extend uncontrolled when once they are started on their course. In the artificial negative atmosphere which I produced in the manner described above, I observed that dead animal and vegetable substances underwent rapid decomposition, and that slight wounds on living bodies became fœtid.

There followed upon these observations other series, in which the effect of the forces of heat and electricity were tried in order to determine whether they would modify the condition of the negative oxygen in respect to its life-sustaining power. The result of these inquiries was to prove that cold added to the negative effect and quickened the narcotism, while a raised temperature, a temperature of 75° F., delayed the narcotism. I also discovered that the passage of electrical sparks through the negative gas restored it to its full activity.

In yet another series of inquiries oxygen, under the influence of the forces of heat and electricity, was rendered active until its sustaining power was destroyed by an opposite process, viz., by the activity with which it entered into combination with the blood. In this manner the action of ozone was observed on animal bodies, and the quickened state of the circulation and over-action which the oxygen in this active state produces were defined. The local action of ozonized air on the air-passages and nostrils in the human subject was tested on Dr. Wood and myself, and the peculiar catarrh and headache which follow the inhalation of ozonized air were described from our own personal experiences.

The whole of these inquiries on the effects of differing physical conditions of oxygen were full of the most useful practical information in reference, it not actually to disease, to the mode in which surrounding atmospheric conditions modify the course of disease. They indicated how men and animals living in the large atmospheric sea are influenced by the action of the great forces of nature on the vital oxygen. They have taught me so much that I could, if I had the means, build a hospital with such appliances for modifying the air, that the course of some diseases might be governed towards recovery by the simple management of the physical conditions of the atmospheric oxygen. In a future and more advanced day of science, this method, the basic principles of which are here sketched out, will be an approved and positive method of treatment. Even now, under the greatest disadvantages, from want of organised plans, I have been able to render useful service to the sick from the experience gained by the experimentation.

BENJAMIN W. RICHARDSON

(*To be continued.*)

THE CRUELTY TO ANIMALS BILL

IN the House of Lords the Government "Vivisection Bill" was discussed in a full Committee on Tuesday. The Marquis of Lansdowne began by a very temperate remonstrance against the Government going so far beyond the recommendations of the Royal Commission on the subject. His speech (which is fairly reported in the *Times*) is by far the best for knowledge and for sense that has yet been made on the Bill, but the provision against which he especially protested—the licensing of places as well as of persons—though warmly supported by Lord Kimberley, still remains part of the Bill. This provision scarcely affects physiologists as such, but may be a means of serious annoyance and hindrance to strictly medical experiments, on, for instance, the contagion of disease or the action of drugs, and would have made the experiments by which Jenner freed the world from the plague of small-pox impossible.

On the first clause Lord Carnarvon stated that the title will be altered from "An Act to Prevent Cruel Experiments upon Animals" to "An Act to Amend the Law relating to Cruelty to Animals," *i.e.*, the Bill no longer pretends to prevent alleged cruelty by scientific men in this country, inasmuch as the charge has not been in a single instance maintained, and only provides that infliction of pain on an animal shall not be screened by the excuse of a scientific object, if the delinquent does not hold a certificate from the Secretary of State that he is a competent person to conduct experiments on animals with all possible humanity and with ability to make them useful.

After some desultory conversation on the definition of the word "animal" (in which one Minister of the Crown committed himself to the opinion that some creatures can feel when their heads are off), the first important amendment was moved by Lord Rayleigh, supported by Lord Cardwell, and accepted, after discussion, by the Ministry. The Bill now, therefore, actually recognises the pursuit of knowledge as equally worthy of respect with that of medicine, and both as entitled to some small share of the immunity accorded to the pursuit of wealth or of amusement. In other words, while the members of the House of Lords have all their lives been vivisecting their animals without anæsthetics *for fun*, they are now pleased to allow physiologists to do the same under many limitations for the advancement of science. This admission was actually opposed by Lord Coleridge in a speech which was forensic and sentimental in the worst sense of the words.

In the fifth clause, exempting cats and dogs from all experiments (even when painless) if undertaken for physiological or medical purposes, the Government accepted the amendment of the Earl of Harrowby, to include horses, asses, and mules under the same provision; but admitted a proviso for these animals being available on special certificate from the Secretary of State when absolutely necessary for some special investigation. On this clause the Earl of Airlie made a sensible speech, but he was not supported by the peers on the Royal Commission, whose report was implicitly condemned. The other clauses were rapidly run through, the Earl of Portsmouth making a successful attempt to obtain some recognition of the necessity of studying the diseases of animals as well as of man. The absurd regulation which, apparently by an oversight, subjected registered and inspected laboratories to the police visitation intended to prevent experiments in unregistered places, was amended without discussion, and the Bill is now probably in the form in which it will be laid on the table of the House of Commons.

Some of its most glaring contradictions and absurdities have been remedied; and, if worked by a reasonable Home Secretary, competent inspectors, and physiologists as humane as the ten or twelve gentlemen who now possess laboratories in the three kingdoms, it will probably do good. But the whole discussion shows the folly of legislating to satisfy unreasoning clamour, and the hopelessness of Parliament dealing in detail with a subject of which almost all its members are profoundly ignorant.

The reasonable plan would have been to register laboratories, and give certificates to persons duly recommended; to inspect them carefully; to withdraw the licence on any abuse being proved; and then to extend "Martin's Act" so as to apply to all cruelty to animals whether domestic or wild, whether performed with a bad object or a good one, so long as the delinquent did not hold a certificate. This would have been in accordance with the recommendations of the Royal Commission would have given far less trouble to Home Secretaries and to physiologists, and would have been a more effectual provision against cruelty. But Parliament has nothing important to do, the Government are in want of popular applause, and very few have the patience or the candour to learn the true state of the case; so that we must be content to hope that the Bill will do less harm than was at first inevitable.

A MUSEUM FOR INDIA AND THE COLONIES

AT the meeting of the International Congress of Orientalists in London in 1874, Dr. Forbes Watson read a paper in which he described (see NATURE, vol. x. p. 421) the plan of an Indian Museum, Library, and Institute. This paper was afterwards published (see NATURE, vol. xi. p. 413). Dr. Watson has just published a pamphlet[1] in which the proposed India Museum and Institute has very naturally expanded into an Imperial Museum for India and the Colonies. What Dr. Watson proposes is that on the site of the old Fife House, on the Victoria Embankment, at the Thames end of the ... Northumberland Avenue, a large and suitable building should be erected, to consist of two divisions, one devoted to the interests and products of India, and the other to those of the various British Colonies. The library and collections which already exist in connection with India are acknowledged to be of great value and importance, and their location in an appropriate building in a central position would greatly increase their usefulness. The arrangement at South Kensington is of course only temporary. Now that Dr. Watson has proposed a plan for an institution which would do for the other colonies what the India Museum and Library attempt to do for India, one wonders why steps have not been taken long ago to supply what appears to be a real want. The subject has, however, engaged for years the attention of those who take an active interest in the Colonies, and several of the Colonies have gone so far as to vote money for the establishment of a Colonial Museum in London. Few people realise the importance of the Colonies to Britain; their extent, population, and the value of their commercial transactions are forcibly exhibited by Dr. Watson in his pamphlet, which we would recommend those to read who wish to have some idea of the value of the Colonies to the mother country. From a scientific point of view such an institution as is proposed would be of great interest and value. British Colonies are to be found everywhere over the surface of the globe, and embrace all climates and every variety of natural productions. Students of natural science would find a properly arranged collection of our colonial productions of great use, especially if combined with a proper library, and no better method could be devised of educating the public generally as to the extent, importance, physical condition, and natural products of "Greater Britain."

Dr. Watson shows that from every point of view, political, commercial, and scientific, the establishment of such an all-embracing Imperial Institute would be of the greatest benefit both to this country and her Colonies, and would no doubt serve to bind them more closely together. We are sure his scheme needs only to be known in its details to recommend itself to the public, and we are confident that if steps were taken to move the proper quarter, the accomplishment of the scheme would be only a question of time. The Colonies themselves are willing to bear a share of the expense necessary, and it would only be fair that this country, through the Government, should meet the Colonists as far as it can.

Into the details of Dr. Watson's plan we have not space to enter. There would, as we have said, be virtually two museums under one building. In the division devoted to the extra-India Colonies, the museum representative of each Colony would be kept distinct, so that the whole would be rather a federation of museums than one museum. Then there would be a Colonial Library and Reading-room; provision would be made for giving a home in the Institution to the Asiatic Society and the Colonial Institute; by means of "Trade Museums," a full representation would be given of Colonial produce, and in the proposed institution the offices of the various Colonial agents now dispersed over London could be established. The advantages of such an Institution are well summed up by Dr. Watson in the following paragraph:—

"The combined India and Colonial Museums, established according to the above plan, would in every way become a living institution worthily representing the past history and the present resources of the British Empire throughout the world. Such an institution would afford not only exhaustive materials for study and research, but would likewise be suitable for reference by the Indian and Colonial authorities, by men of business or of letters, and by officials or emigrants intending to proceed to India or the Colonies. Thus it would be instrumental in furthering actual work or business, whether scientific, political, or commercial. At the same time, through its co-operation with the Asiatic Society and the Colonial Institute, through its reading-room, its lectures and publications, through the Trade Museums and other typical collections distributed all over the country, as well as throughout the most important places in India and the Colonies, all the information would be rendered available to the whole P . . ."

[1] "The Imperial Museum for India and the Colonies" By J. Forbes Watson, M.D., &c., Director of the India Museum. (Allen and Co.)

FERTILISATION OF FLOWERS BY INSE

XIV.

Flowers Fertilised by the Wings of Butterfl

IN my former articles many plants are referred to which are fertilised by butterflies, whose proboscis, head, legs, or whole underside comes into contact with the anthers and stigmas of the flow is visited; but hitherto no plant has been known which is fertilised by the fluttering wings of butterflies. My brother, Fritz Muller (Itajahy, Prov. St. Catharina, Brazil), has lately observed a species of *Hedychium* (Piperaceæ) whose bright red scentless flowers, opening in the morning, are wonderfully adapted to this manner of fertilisation. I give his description, as far as possible, in his own words.

The flowers of this Hedychium are collected in groups of 4–6, which are enveloped by a common bract; in every group only one flower is ever developed at the same time, this commonly fading before the next one has opened. The groups of flowers are arranged in alternating whorls, each consisting of three groups (Fig. 89); the spike thus formed reaches 0·25 metre in length, and is composed of six longitudinal rows of flowers, each row containin 8.

The corolla tubes, about 0·03 m. long, 0·5 and 1 mm. wide, are completely enclosed by the very firm common bract; moreover, each by its calyx closely embracing it, by its special bract and partly by the bracts of the older flowers of the same group. Thus the honey, which on the morning of the first day fills up about one-third, on the morning of the second day about two-thirds of the length of the tube, is excellently protected from being stolen by piercing the tube, of which some Apidæ, especially Hylocopa, are exceedingly fond. The flowers are placed nearly horizontally, the stamen a little above, the lip a little below a horizontal plain intersecting the entrance of the honey-tube. The lip, which in other species of Hedychium is expanded level and almost sessile, is here long stalked, and rolled up into a channel of 0·01 m. in length provided with a funnel-shaped entrance. The entrance of the lip-channel (Fig. 89 *A*) being about equally distant from the two longitudinal rows of anthers and stigmas Fig. 89 (*B*, *C*) between which it is situated, both rows are alike struck by the wings of the butterflies flying on and off.

The filament is 47 mm. long on the forenoon of the first day and somewhat bent upwards, so that the pollen-covered side of the anther looks outwards or even a little

[1] Continued from vol. xiii. p 294.

upwards (hence the stigma looks upwards or even obliquely backwards); on the morning of the second day it is 50 mm. long, straight, and the stigma looking forwards; by the morning of the third day the flowers bend aside and wither. Consequently on the first day the anthers, on the second day the stigmas are more liable to be struck by the wings of the butterflies, although the stigmas seem to be capable of being pollinated already during the opening of the flower. The pistil, as in other species of Hedychium, is inclosed in a completely closed channel of the corolla tube (Fig. 90) and of the filament (Fig. 91); the funnel-shaped stigma (Fig. 92), secreting plenty of fluid and bordered with hairs (Fig. 93), slightly overtops the anther (Fig. 89, *st.*).

By the morning of the second day all bees and butterflies with a proboscis of more than 10 mm. long would be enabled to obtain at least a little portion of the very sweet honey from out the opening of the corolla-tube; whereas from the more conveniently situated opening of the lip-tube the full store of honey can be reached only by a single species of the butterflies of Itajahy (as far as their proboscides have been measured by my brother), namely, the males of *Callidryas Philea*, with a proboscis from 36 to 43 mm. long.[1]

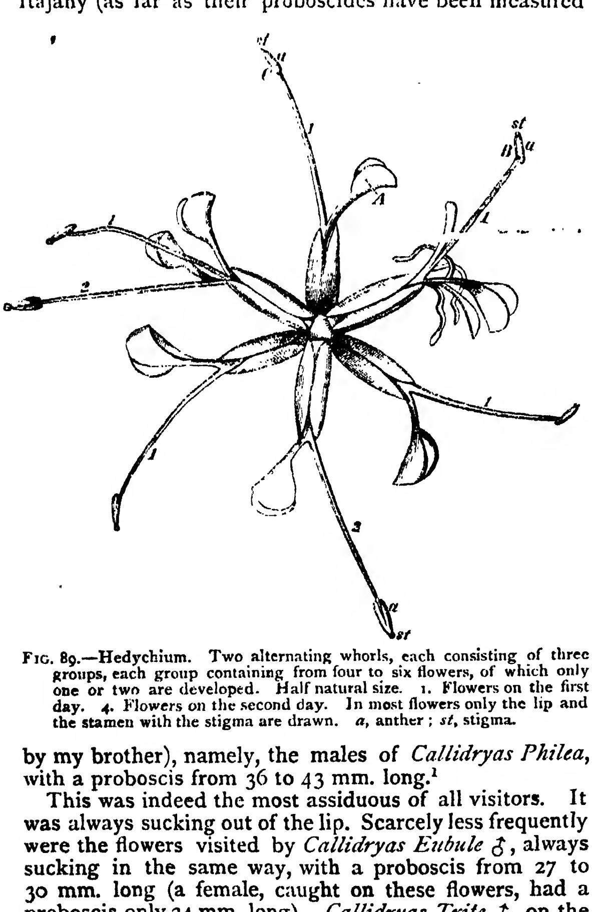

FIG. 89.—Hedychium. Two alternating whorls, each consisting of three groups, each group containing from four to six flowers, of which only one or two are developed. Half natural size. 1. Flowers on the first day. 4. Flowers on the second day. In most flowers only the lip and the stamen with the stigma are drawn. *a*, anther; *st*, stigma.

This was indeed the most assiduous of all visitors. It was always sucking out of the lip. Scarcely less frequently were the flowers visited by *Callidryas Eubule* ♂, always sucking in the same way, with a proboscis from 27 to 30 mm. long (a female, caught on these flowers, had a proboscis only 24 mm. long). *Callidryas Trite* ♂, on the contrary, with a proboscis 18 to 20 mm. long, seems always to suck immediately out of the corolla-tube. *Callidryas Statira* ♂ (19 to 21 mm.) mostly sucks in the same way; but sometimes also from out the lip. *Callidryas Argante* being very rare during the flowering time of this Hedychium (towards the end of January) was only occasionally seen visiting its flowers, and it was not observed in what way it reached the honey. Dark yellow, orange, scarlet, red, are the favourite colours, not only of the Callidryas but likewise of the *Agraulis* (*Dione*) and of some species of *Papilio*; of the former, *Agraulis vanillæ* (proboscis 15 mm.) visited the flowers several times, but soon flew away again. Of species of Papilio, *P. Thoas* (26 mm.) appeared especially frequently, as also several times *P. Palydamas* (24-25 mm.), *P. Cleotas* 22-23 mm.) three times, and once *P. Protodamas* (?) (22 mm.); these mostly fluttered upwards along the rows of flowers without settling down; it was not distinctly seen from which opening they obtained the honey.

[1] The proboscis of the female seems to be not so long; in two females measured by my brother it did not exceed 35 mm.

Another adaptation of the flowers to cross-fertilisation by butterflies must be mentioned. A wing of a butterfly is a tolerably smooth plain, moving rapidly when flying; the pollen-grains of Hedychium are likewise smooth; these peculiarities are ill adapted to each other; but this inconvenience is removed by the anthers not bursting, but their anterior-surface dissolving into a layer of slime which covers the pollen-grains and glues them to the wings.

Of Apidæ my brother once saw *Xylocopa*; it attempted to suck from the lip, but after having made some fruitless trials flew away again. He repeatedly met with *Bombus violaceus* and *Cayennensis*, rarely, however, compared with their frequent visits to other flowers, for instance, the neighbouring bushes of Buddleia. They sucked from out the corolla tube. *B. violaceus* was several times observed to alight on the lower flowers of a longitudinal row, climbing from there up the row more or less completely, then flying to another spike. In consequence of this systematic manner in which the most intelligent bees explore the flowers of a plant, the fertilisation by bees of a plant with such a number of flowers as our Hedychium

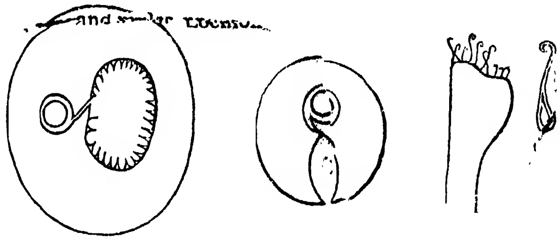

FIG. 90. FIG. 91. FIG. 92. FIG. 93.

FIG. 90.—Transverse section of the corolla-tube, 15 : 1. FIG. 91.—Transverse section of the filament enclosing the pistil. FIG. 92.—The stigma bordered with hairs. FIG. 93.—A single one of these hairs.

must be by far less advantageous than the fertilisation by butterflies. Suppose a specimen of this Hedychium bearing twenty spikes, each with fifty flowers, a humble-bee would be likely to visit 1,000 flowers without effecting a single cross-fertilisation between different plants, consequently without any profit for the plant, which is sterile with its own pollen. On the contrary, on flowers copiously visited by butterflies, the same butterfly will rarely visit a greater number of flowers of the same plant continuously; and this holds good, not solely, as Delpino has already remarked, with females which are followed by the males. On a Hedychium, males of Callidryas only were flying (females being then very rare), but, nevertheless, as soon as any butterfly was approached by another of the same or even of a different species, it flew up, ran and whirled with it about in the air, and then alighted commonly on another bush.

Lastly, there appeared repeatedly several species of humming-birds, one of which was so absorbed in sucking the honey that it could be caught with a net, which my brother had never before succeeded in doing. In the corolla-tube of this Hedychium small insects have never been found by my brother; the perseverance with which the humming-birds made use of its flowers proves, therefore, in case such a proof should still be needed, that these birds were here searching for honey.

It may be remarked in addition that humming-birds are far less exclusively attracted by the bright red colour of flowers than Callidryas; and, as these butterflies are

those which are found in greatest numbers in Itajahy (*Acræa Thalia* only perhaps equalling or even surpassing them in number), the frequent occurrence of orange-coloured or scarlet flowers in that country is probably less an adaptation to humming-birds than to this fondness of Callidryas The red Salvia, Canna, the orange-coloured species of Lantana, *Epidendron cinnabarinum*, &c, are assiduously visited by Callidryas.

Lippstadt, May 13 HERMANN MÜLLER

LOAN COLLECTION OF SCIENTIFIC APPARATUS

SECTION—MECHANICS

PRIME MOVERS[1]

WE now come to Newcomen, who I think may fairly be looked upon as the father of the steam engine in its present form No 1,942 is a model of his engine, which is further illustrated by a rare engraving (of 1712) the property of Mr Bennet Woodcroft

Here we have the steam boiler, the cylinder, the piston and rod, the beam working the pumps in the pit, the injection into the cylinder and the self acting gear, making altogether a powerful and an automatic prime mover

That conscientious writer, Belidor, to whom I have already frequently referred, says, that he learns of one of these machines having been set up in the water works on the banks of the Thames at York buildings I may say to those who are not aware of it, that these works were situated where the Charing Cross Station now stands On a Newcomen engine being erected in France at a colliery at Fresnes, near Condé, Belidor paid several visits to it in order that he might understand its construction thoroughly, and be thereby enabled to explain it to his readers. He has done so with a minuteness and faithfulness of detail, in description and in drawings, that would enable one to repeat the engine This engine had a 30 inch cylinder with a 6 feet stroke of the piston and of the pumps The boiler was 9 feet in diameter and 5½ feet deep in the body, it had a dome which was covered with masonry 2 feet 6 inches thick to hold it down against the pressure of the steam It had a safety valve (the Papin valve) which Belidor calls a "Ventouse," and says that its object was to give air to the boiler when the vapour was too strong It had double vertical gauge cocks the function of which Belidor explains, it made fifteen strokes in a minute, and he says that being once started it required no attention beyond keeping up the fire, that it worked continuously for forty eight hours, and in the forty eight hours unwatered the mine for the week, whereas previously to the erection of the engine the mine was drained by a horse power machine, working day and night throughout the whole week and demanding the labour of fifty horses and the attendance of twenty men to keep the water down I should have said that the pumps worked by the steam engine were 7 inches bore and were placed 24 feet apart vertically in the pit which was 276 feet deep, and that each pump delivered into a leaden cistern from which the pump above it drew.

After having given a most accurate description of the engine, Belidor breaks out into a rhapsody and says (I will give you a free translation) "It must be acknowledged that here we have the most marvellous of all machines, and that there is none other of which the mechanism has so close a relation to that of animals Heat is the principal of its movements, in its various tubes a circulation like that of the blood in the veins is set up, there are valves which open and shut, it feeds itself, and it performs all other functions which are necessary to enable it to exist"

Smeaton employed himself in perfecting and in properly proportioning the Newcomen engine, but it was not until James Watt that the next great step was made, that step was as we all know the doing away with condensation in the cylinder, the effecting it in a separate vessel and the exclusion of the atmosphere from the cylinder These alterations made a most important improvement in the efficiency of the engine in relation to the fuel consumed, but they were so simple that I doubt not if examiners into the merits of patents had existed in those days Mr Watt would have had his application for a patent rejected as being "frivolous" We have here from case No 1,926, a model made by Watt which appears to be that of the separate condenser and air-pump, we have also 8B which is a wooden model made by Watt of a single acting inverted engine having the top side of the cylinder always open to the condenser, and a pair of valves by which the bottom side of the piston can be put into alternate connection with the boiler and with the condenser, the contents of which are withdrawn by the air pump 9B from the same case is a model of a direct acting inverted pumping engine, made in accordance with the diagram 8B 11 is a model of Watt's single acting beam pumping engine, while 2B is a model of Watt's double acting beam rotary engine 101 from the same case is Watt's model of a surface condenser To Watt we owe, condensation in a separate vessel, exclusion of the air from the cylinder, making the engine double acting, employment of the steam jacket, and employment of the steam expansively, the parallel motion, the governor, and in fact all which made Newcomen's single acting reciprocating pumping engine into that machine of universal utility that the steam engine now is, and not only so, but Watt invented the steam engine indicator which enables us to ascertain that which is taking place within the cylinder and to see whether or not the steam is being economically employed I have on the table before me a very excellent model of German manufacture No 2,137, illustrating an inverted direct acting pumping engine in its complete form, and I have also a model of French manufacture, the cylinder and other working parts of which are in glass, this shows a form of Watt rotary beam condensing engine at one time in common use

I do not say, however, that Watt was the first to make the suggestion of attaining rotary motion from the power of steam Leaving out of consideration Hero's toy, Papin, as I have remarked, hoped to get rotary movement second hand by working a water wheel with the water that had been raised by his steam-engine, moreover, as early as 1737, Jonathan Hulls proposed to obtain rotary motion from a Newcomen engine and to employ that motion in turning a paddle wheel, to propel a tug boat which should tow ships out of harbour, or even against an adverse wind I have before me one of the prints of his pamphlet and in order that you may better appreciate his invention I have put an enlarged diagram upon the wall and I think I may take this as the starting point for saying a few words about the steam engine as a prime mover in steam vessels

We have in the collection, No 2,150 Symington's engine tried upon the lake at Dalswinton in 1788 Here a pair of single acting vertical cylinders give, by the up and down motion of their pistons, reciprocating movement to an overhead wheel, this wheel gives a similar motion to an endless chain which chain is led away so as to pass round two pairs of ratchet wheels loose upon two paddle shafts By the use of a pair of ratchets the reciprocations of the chain are converted into rotary motion in one direction only and that the driving direction of the two paddle wheels placed one behind the other Symington's arrangement for obtaining the rotary motion always in one direction of his two paddle wheels is very similar to that proposed by Jonathan Hulls for his single stern wheel Want of time forbids me to do more than just to allude to the names of Hornblower and Wolff in connection with double cylinder engines, engines where in the expansion of steam is commenced in one cylinder and continued in another and a larger one

I wish to say a few words which will bring before you the changes that have been made within a very few years in the construction of the marine engines I may observe that when I was an apprentice the ordinary working pressure of steam, except in the double cylinder engine, was only 3 lbs above atmosphere, and that there was in a marine boiler more pressure on its bottom when the steam was down, due to the mere head of water in the boiler, than there was pressure in the top when the steam was up, due to the force of the steam, whereas now condensing marine engines work commonly at 70 lbs, and there is a boat under trial where the steam is, I believe, as high as 400 lbs

To those who are curious on the subject, I would recommend a perusal of two blue books, one being the evidence taken before a Parliamentary Commission in 1817, and the other before a Parliamentary Committee in 1839, they will find there the weight of evidence to be that the only use of high pressure steam is to dispense with condensing water, and that as a steamboat must always have plenty of condensing water in its neighbourhood, no engineer knowing his business, would suggest high pressure for a marine engine.

I have before me a model of a pair of engines which, although

[1] Address delivered by F J Bramwell, C E, F R S, one of the vice presidents of the Section, May 25 Continued from p 161

they were made not so very long ago (for I saw them put into the ship), have nevertheless an historical interest. This model shows Maudslay's engines of the *Great Western*, the first steamer built for the purpose of crossing the Atlantic. I think I am right in saying that 7 lbs. steam was the pressure employed in that vessel, and in order to extract the brine from the boiler it was necessary to use pumps as the pressure of the steam was not sufficient to expel the brine and to deliver it against the pressure of the sea.

Time does not permit of my touching upon the various improvements in boilers, condensers, expansive arrangements, and other matters which have gradually been introduced into our best engines for land and for ocean purposes. I have hung upon the wall a rough diagram showing a pair of oscillating engines as applied to driving a paddle steamer, and another showing a pair of inverted compound cylinder engines to drive a screw propeller; a model of such a pair of engines with surface condensers and all modern appliances (being Messrs. Rennie's engines for the P. and O. Company's S.S. *Pera*, by which I have had the pleasure of travelling) is now before me.

I will conclude this part of the subject by saying that to the combination of science and sound practice is due the fact of the consumption of coal having been reduced from 5 lbs. per gross indicated horse-power per hour to an average of 2½ lbs. and, in exceptional instances, to as small a quantity as 1¼ lbs. per horse per hour.

Let us now devote a little of the time that is left to the consideration of the locomotive on the common road as well as on the railway. I have before me No. 2,145, a model of the actual engine of Cugnot, in the Conservatoire des Arts et Métiers, which, in 1769, journeyed—slowly, it is true, but did journey and did carry passengers—along the roads in Paris.

It is a most ingenious machine; it has three wheels, and the motive power is applied to the front, the castor, or steering wheel, so that engine and boiler turn with the wheel precisely as, within the last few years, Mr. Perkins has caused the engine and boiler to turn with the steering wheel of his three-wheeled common road locomotive. The steam causes the pistons in a pair of inverted single acting cylinders to reciprocate, and their rods, by means of ratchet wheels, give rotary motion to the castor wheel, and thus propel the carriage. I think there is no doubt but that we must look upon this engine of Cugnot as the father of steam locomotion, as we must regard Symington's engine as the parent of marine propulsion. I have before me No. 1,926, Trevithick's engine of 1802. I have also before me a Blenkinsop rail, one that has been in actual use for many years, provided, as you will see, with teeth, into which a cogged flange on the side of the driving-wheel is geared to insure that tractive force should be obtained. This plan has been revived, within the last few years, to enable the steam locomotive to climb the Righi. A sketch of the Righi engine and rail is on the wall. It will be seen that the teeth instead of projecting from the side of the rail, are ranged between two parallel bars like the rungs of a ladder.

On the ground floor of the exhibition we have the veritable "Puffing Billy," an engine which began work in 1813, and got along without the aid of cogs by mere adhesion upon plain rails; it is a rude looking machine, but it laboured up till the date of the last Exhibition, doing its work for forty-nine years on the railway belonging to the Wylams Colliery, and, as tradition says, interesting George Stephenson, who, as a boy, saw it in daily operation.

On the ground floor, also, we have 1,954, the "Rocket," with which seventeen years after the starting of "Puffing Billy" George Stephenson carried off the prize in the Manchester and Liverpool Railway competition. The leading particulars of this engine are as follows:—A pair of 7½ inch cylinders 1′ 5″ stroke, placed at a slight inclination driving 4′ 6″ wheels, the boiler, multi-tubular, having twenty-four three and a half inch tubes, while the fire is urged by the waste blast. Before alluding to this I ought to have mentioned that in one of the Blue Books to which I have called your attention—that which gives the evidence before the Commission in the year 1817—there is a statement by a witness that in those parts there are machines called locomotives, &c.

Once more I am compelled to say that time will not admit of my entering into any detail in respect of the modern locomotive, except to remark that by the aid of excellent boilers, of high-pressure steam (140 lbs. to the inch) of considerable, although rather imperfect expansion effected by the link motion, there is provided for the use of our railways a machine which in the "passenger" form is competent to travel with ease and safety sixty miles an hour, and in the "goods" form is competent to draw a load of 800 to 1,000 tons, and to attain these results with a very commendable economy in fuel. I have put on the wall two diagrams of locomotives of the convenient form for local traffic that we call tank engines, and I have before me No. 1,957*a*, a most beautifully made sectional working model of a Russian six wheeled "goods" engine.

Within the last twenty years another description of steam-engine has acquired a prominent and important place among our prime movers, I allude to the portable engine, or to the portable engine in its more complete form of a self propelling or traction engine. The general construction of these machines borders closely upon that of the locomotive. Very great attention has been paid to all their details, and the Royal Agricultural Society of England, by their excellent arrangements for periodical trials, have stimulated engineers to devote their best energies to the subject. No. 1,942 is a model of one of Aveling and Porter's common road traction engines, capable also of acting as a source of power for driving farm yard machinery or for effecting steam-ploughing. Upon the wall I have placed rough diagrams of another kind of traction engine—a kind wherein india rubber tires are used; this is manufactured by Messrs. Ransome, Sims, and Head, and I have also placed there diagrams of the ordinary portable engine and of another most useful kind of portable engine, viz., the steam fire engine. I have there likewise a sketch of Hancock's common road steam coach which for so many months regularly plied for hire from the Bank to Paddington in opposition to the ordinary horse omnibus. Hancock's carriage was a vehicle which, in my judgment, has never since been surpassed, and I am sorry to say never to my knowledge equalled as regards the various points which should be attended to in making a steam carriage to circulate safely among horse-traffic.

There is another way in which steam may be employed as a prime mover. We saw that water in the form of the Trombe d'eau could be caused to induce a current in air and thereby to blow a forge fire, and that a rapid stream induces a current in other water, and thus drains marshy lands. Similarly steam can be caused to induce a current in water and thereby impel the water so as to raise it to a height or to force it as feed water into a boiler against a heavy pressure. When used for a mere pumping apparatus, such a mode of employing steam is very wasteful, because the steam is condensed by the water in large quantities and the water is needlessly heated at the expense of the steam; but when used in feeding a boiler into which, thus, the whole of the heat is taken, this objection does not apply. By means of that most elegant and scientific apparatus, the Giffard injector, it is possible by a jet of steam to economically induce a current in surrounding water, powerful enough to take the condensed steam itself and the water into the boiler from which the steam had previously issued. No. 1,976, which I have before me, is a sectional model of a Giffard injector.

I believe it was I who first gave a popular explanation of the principle of action of the Giffard injector, and although a scientific congress is probably not the place for a popular explanation, I will venture to repeat it. The principle may be summed up in one word, "concentration." The steam that issues from an orifice of an area of 1, when condensed, has a sectional area (according to the original pressure of the steam) of only $\frac{1}{200}$th or $\frac{1}{400}$th or $\frac{1}{800}$th as the case may be, thus the velocity remaining the same and the weight the same the energy of the steam issuing from an area of 1, is concentrated 200, 400, or 800 times upon the area due to the smaller transverse section of the liquid stream.

This concentration of energy is far more than sufficient to enable the fluid stream to re-enter the boiler from which the vaporous stream started, and so much more than sufficient, that it may be diluted by taking with it a certain quantity of water, which was employed in the condensation of the steam, and is required for the feeding of the boiler.

With a view to obtaining economy in fuel many attempts have been made to employ some other agent than steam as the means of developing the power latent in fuel, but it is imperative that I should dismiss these with a mere enumeration. A very interesting engine of this kind (because, excluding Hero's toy and smoke jacks, it is so far as I know the first proposition for obtaining rotatory motion by the aid of heat), was the fire wheel of M. Amonton, of which an account is to be found in the first volume of the "French Academy of Sciences," for the year 1699. On referring to that volume I do not see that it is stated

in terms, the machine was ever put to work, although it is said that M. Amonton made many experiments to convince the Academy of the practicability of his invention. M. Amonton proposed to have a metallic wheel revolving on a horizontal axis; the outer rim of the wheel was to be divided into a number of separate air cells, each of which had a channel so as to communicate with other cells, water-cells, arranged round the wheel nearer to the centre than the air-cells; the air cells as they passed over a fire were to be heated, and the air was to drive this water up to one side of the wheel, so as to keep that side always loaded, and thus give the wheel a tendency to revolve. The cells after leaving the neighbourhood of the fire were to be cooled by passing through water to re-contract the air ready for the next operation.

No. 1,940, which is before me, is a model of Stirling's hot-air ..., but time does not remain to describe it.

Besides hot-air engines, we have had engines working by the explosion of gunpowder, and others working by the explosion of gases. No. 1,945 is Langen and Crossley's gas engine, from which I believe extremely excellent results have been obtained.

I will now ask you to look at a tabular statement which shews the consumption of fuel in some agricultural engines, when under trial, expressed in pounds per horse-power per hour, and also in millions of pounds raised one foot high by the consumption of 1cwt. of coals. I told you how excellent were the results at which our agricultural engineers had arrived; you will see that one of those machines, working with 80lbs. steam, and of course without condensation, has developed, not a gross indicated horse-power, but an actual dynamometrical horse power, for 2.79lbs. of coal per horse per hour, giving a duty of as much as 79½ millions. This high result was obtained by the excellence of the boiler and of the combustion, as well as by that of the engine. If you look at the column of evaporation you will find that as much as 11.83lbs. of water were converted from the temperature of the boiling point into steam by the combustion of 1lb. of coal; this was due, not to the merits of the boiler alone, but to the extraordinary ability of the stoker, and to the care and labour bestowed, a care and labour far too expensive to be employed in practice. But should not we engineers endeavour to ascertain whether we cannot by mechanical means, practically, with certainty and cheapness, procure an accuracy of combustion as great, or even greater than that which can be got by the almost superhuman attention of a highly-trained man, who at the end of four hours of such work is utterly exhausted? Many forms of fire-feeders have been attempted and used with more or less success, but I cannot help thinking that in order to obtain the accurate proportioning of air and fuel, by which alone we can get efficient and economical combustion, we shall have to turn our attention in the direction of dealing with the fuel in a comminuted state, either by converting it into gas, as is done by our president, Dr. Siemens, by availing ourselves of liquid fuel, or by employing the process of Mr. Crampton, and making the fuel into an impalpable powder, that may be driven into the furnace by the air which is there to consume it.

By these, and by other means, we may hope to improve combustion. By strict attention to the proportioning of the parts of the boiler we may hope to make the best use of this improved combustion. By higher initial pressure, by greater expansion, and by the general employment of condensation, wherever practicable (and by the use of the evaporative condenser there are very few cases in which it is not practicable), we may trust that the steam-engine, even on its present principle, will be rendered more economical than it has ever yet been, and may give us more than that one-eighth or one-ninth of the total force residing in the fuel which now alone we get under the very best and most exceptional conditions. A large loss, however, must with steam-engines, as we now know them, always be incurred. We cannot hope to deal with initial pressures and temperatures corresponding with steam of a density equal to that of water, nor to carry expansion down to the point where ice would be formed in the condenser. But wonderful as the steam-engine is, worthy as it was and is of Belidor's eulogium (which I read to you), we know it is not the only heat motor, and we are aware that there are other forms of such motors which, theoretically at all events, promise higher results.

By improvements in the existing steam engine, by the invention and development of other heat motors, by the employment of the power of water and of wind, either as principal motors or as auxiliaries, we may look to further progress in the machines—the subject of my address—"Prime Movers."

I have brought before you, of necessity hastily, and therefore (and also on account of my own incapacity for the task) imperfectly, the leading improvements which have been made in prime movers from the date of the water-wheels of Vitruvius to the best-devised steam-engines of our own day. These improvements have been effected by men like Papin, Savery, Newcomen, Watt, Symington, Stephenson, and others, who were not mere makers of engines, but were men full of an ardent love of their noble profession, who followed it because of the irresistible attraction it possessed for them; followed it from their boyhood to their grave, and in that very following found their great reward. These men undoubtedly possessed that combination of science and practice, which combination, Dr. Tyndall has told us, is necessary if either science or practice is to continue to live, for, to use his expressive language, without this combination they both die—die of atrophy; the one becomes a ghost, the other a corpse.

We have every reason to believe that this combination will rapidly become even more fully developed, not only in the engineers of the present day, but in those of the next and of succeeding generations, and to such men as these we may trustfully leave the continued improvements of prime movers, resting content with the knowledge that a more general application of these machines must of necessity follow such improvements, and that the day will soon dawn when in no civilised country will there continue to be the temptation to employ intelligent humanity in the brutal labour of the turnspit, or of the criminal on the treadwheel.

OCEAN CIRCULATION[1]

THE present theories with regard to ocean circulation do not appear to account for many of the phenomena with which we are acquainted, and my object in this paper is to state very briefly my own opinions, with a view to provoking discussion, and, in this way, to forward the knowledge of a very difficult but interesting subject. I believe that there are at the present moment two rival doctrines, viz.:—

1. One which attributes all currents to the influence of the winds.
2. Another which attributes all ocean currents to gravitation.

I entirely disagree with the first doctrine, and shall address my remarks to the second. I quite think that ocean circulation is the result of gravitation, but, contrary to what I believe to be the present opinion, I hold that the cold feeding streams flow in a wave from the surface of the Polar oceans, and not from the bottom.

The points that I wish particularly to suggest for consideration are as follows:

1. That all ocean currents run from a higher to a lower level.
2. That the upward pressure produced in the equatorial regions by the constant inflow, at the bottom, of water from the Polar regions owing its high specific gravity to its contraction from cold, and, *vice versâ*, the constant inflow at the bottom of the Polar regions, of water flowing from the equatorial regions and owing its high specific gravity to its salinity, must, these streams flowing from a higher to a lower level, tend to elevate the lighter surface-water and drift it down a slightly inclined plane as a surface current.
3. That the primary cause of the origin of all ocean currents is the change in the specific gravity of sea water from one of the following causes, viz.:

(*a*) Evaporation, the vapour arising from the surface being fresh, and leaving its saline constituents behind it.

(*b*) The excess of precipitation over evaporation, particularly in the Polar seas, which by admixture with the surface-water increases its freshness.

(*c*) The expansion of surface-water through heat.

(*d*) The contraction of sea-water through cold.

It is generally admitted that currents of both air and water flowing from the equator to the poles having an excess of easterly momentum due to the velocity of rotation of the earth's surface in low latitudes as compared with the lesser velocity in high latitudes,[3] must outstrip the earth's motion, and consequently

[1] More particularly with reference to the North Atlantic Ocean, being an abstract of a paper read to the Caterham Literary Society in March last.

[2] I hold it to be impossible that you can have any such thing as an ocean level unless the different strata or layers of water from the equator to the poles are not only isometrical and isothermal, but are also of equal specific gravity; whereas the known ranges of variation of both temperature, salinity, and depth of different strata of sea water vary much in different places and in different oceans. There is a constant disturbance of equilibrium, and the constant effort to restore and equalise it produces the currents.

[3] The rotatory velocity of the earth's surface being about 1,440 feet per second at the equator, 720 feet per second in 60° of latitude, and ... zero at the poles.

flow in an easterly direction; and, on the other hand, currents of both air and water flowing from the poles towards the equator must for the same reason lag behind, and consequently appear to flow in a westerly direction. From this I argue that the cold currents from the Arctic regions to the equator do hug the western shores, and therefore cannot possibly supply the cold streams on the eastern side of the North Atlantic Ocean, south, at all events, of 50° of lat.; but that the supply must come from the Antarctic Ocean; and, on the other hand, from the same cause, that the cold water on the eastern side of the South Atlantic Ocean is water from the Arctic Ocean which underflows the equatorial stream, and as it approaches the African coast, has a portion of its stream thrown upwards towards the surface, which accounts for the surface-water of the equatorial stream near this coast being some degrees colder than that of the Guinea current to the northward of it.

I need not say that every gallon of water that flows into the North Atlantic from the South Atlantic Ocean must be returned to it in some way, either by a surface or an under-current; and I think I may safely argue that there are no surface-currents sufficient to account for the return of the volume of Antarctic water, and that, therefore, a large portion of the water returned must be from the Arctic basin, and must flow in the manner which I have previously indicated.

The surface-water in these warm regions is lifted by the inflow below it of colder and therefore heavier water from the two polar seas, it then flows off as a surface-current, and the portion of it flowing towards the north pole is deflected by the constant easterly trade winds and obliged to flow westward along the north coast of South America; a large portion of it flowing through the Carribbean Sea into the Gulf of Mexico, and thence through the Gulf of Florida. If we estimate the width of this part of the stream to occupy in the narrows thirty-two miles out of a total breadth of forty-two miles, and its depth at 200 fathoms, its velocity at an average rate of four miles per hour, *i.e.*, in the narrows, it is equal to a stream 2,650 miles wide, 60 feet deep, and running at the rate of one mile per hour, which shows that it is not the mere rivulet it is sometimes described to be. I am aware that its average rate is now said to be less than four miles per hour; but I myself travelled through the Gulf of Florida twice a month for two years, once a month when bound to the northward, keeping in the strength of the stream, and I cannot help thinking that its strength is now very much undervalued, probably in consequence of its rate, as noted, not being strictly confined to the narrows.

This stream is uplifted as it flows out of the northern entrance of the Gulf of Florida by the inflow beneath it of colder and heavier water flowing in the contrary direction from the Arctic Pole; and this, in my opinion, accounts for the arched form of the surface of the Gulf Stream as noted by Maury. Off Hatteras it is only 100 fathoms deep, and being beyond the influence of the trade winds, its easterly momentum, due to its northerly flow, inclines its course to the northward and eastward. When it gets to the northward of 40° of lat., which it does in about 50° of W. long., it appears to spread itself out over the ocean. Now this warm stream has been giving out volumes of vapour during the whole of its northward course, and has from this cause been gradually getting salter and salter; and as it gets shallower, this effect must naturally be greatly increased, besides which the temperature of the stream begins rapidly to decrease. It, in my opinion, then flows onwards towards the pole, gradually losing temperature until it meets with Polar water, which, though colder, has, owing to its admixture with glacial water, a less specific gravity than itself; it then dips below the surface, and, getting colder and colder, runs with great rapidity to the bottom of the Polar basin.

I must now try and prove that this is what takes place, and for this purpose I shall quote from Maury and Capt. Nares.

Maury, vol. ii. pp. 184 and 185.—"Capt. Duncan says, Dec. 18, 1826:—

"It was awful to behold the immense icebergs working away to the north-east from us, and not one drop of water to be seen; they were working themselves right through the middle of the ice.

"Feb. 23, lat. 68° 37′ N. long., about 63° W., about 3 P.M., the iceberg came into contact with our floe, and in less than one minute it broke the ice. Again he says, the berg was drifting at the rate of about four knots, and by its force on the mass of ice was pushing the ship before it, as it appeared, to inevitable destruction.

"Passed Midshipman S. P. Griffin, who commanded the brig *Rescue* in the American searching expedition after Sir John Franklin, informs me (*i.e.*, Maury) that on one occasion the two vessels were endeavouring to warp up to the northward in or near Wellington Channel, against a strong surface-current, which of course was setting to the south; and that whilst so engaged, an iceberg with its top many feet above the water came drifting up from the south, and passed by them like a shot, although they were stemming a surface current both against the berg and themselves. Such was the force and velocity of the under-current, that it carried the berg to the northward faster than the crew could warp the vessel against a surface- but counter-current."

Capt. Nares, in the Report of the *Challenger*, No. 2, says:—

"All the observations, however, agree in denoting that at a depth of from 80 to 200 fathoms there is a stratum of cold water lying intermediate between the superheated surface-water and the warm underlying layer, which is evidently the continuation towards the cold regions of the main oceanic flow of water."

If Capt. Nares had continued his investigations to the southward of 65° 42′ S., and it had been possible to trace this warm layer as it gradually decreased its temperature, I have no doubt that its course might be traced to the bottom.

I could adduce further confirmation of these views if space would allow me. If my readers will look at a globe, they will readily see that the Arctic Ocean is comparatively a very small sea, and that the effect of large volumes of salt water pouring into the bottom of the Polar basin must elevate the lighter, because fresher, surface-water, and consequently cause a constant outflow towards the equator. A very large stream, known as the Labrador current, runs off as a surface-current through Davis Strait, one fork dipping below the surface, at some seasons of the year, as far to the southward as 42° N., and then underrunning the Gulf Stream: and the other fork, running over the tail of the great bank, and flowing in-shore of the Gulf Stream, runs along the American coast as far south as Florida. The velocity and boundaries of all these streams vary greatly at different seasons, that is to say, the position of the sun affects the ocean as much as it does the atmospheric currents.

A further argument in favour of the cold currents flowing from the surface at the poles is that this is exactly what happens in the circulation of the atmosphere. The north-east and south-east trades, which are generally admitted to be Polar currents, descend on the equatorial side of 30° of lat.; besides in no other way that I can see can you obtain a sufficient motive power. A *primum mobile* depending on the lateral pressure of a column of Polar water as opposed to the lesser weight of a column of temperate or of equatorial water, assuming the length of the ocean (counting say from 70° of lat. to the equator) to be 4,200 miles, and its mean depth to be 3 miles, *i.e*, a length of 1,400 times its depth, appears to me to be a very insufficient power to move the volumes of water which we know to be constantly circulating between the equator and the poles. (An ordinary sheet of note paper has a length equal only to 928 times its depth.) If, however, it is allowed that the cold streams flow from the surface, and that they do not dip till they reach 70° of lat.[1] (the Labrador current, as before stated, dips much further towards the equator, sometimes in 42° N), you have still a fall of nearly 3 feet 7 inches per mile of lat. to the equator.[2] I have said sufficient to indicate very briefly my opinions. The arguments I have recently read on this subject appear to be based on the idea that currents flow in one lateral sheet from the pole to the equator. If they did this, there would be no reason why the surface-currents should not flow in a similar way. But they do not; and, if of the depth lately suggested, *i.e.*, 3,000 feet, the Arctic basin could not receive them if they did. The *Challenger* observations seem to me to entirely disprove this view of the subject.

There is a wonderful similarity between oceanic and atmospheric circulation, which I propose more specially to point out at some future time. If we wish to know how the N.E. trades and the S.W. winds pass one another in the upper regions of the atmosphere, let us question the currents of the ocean, and the Labrador current will suggest an intelligible reply. If, on the other hand, we want to know what is the system of ocean circulation, let us ask the currents of the atmosphere; and the Polar currents (*i.e.*, the trade-winds) and the equatorial currents (*i.e.*, the westerly winds of the temperate zones) will strongly suggest to us the answer. It is quite true that there is no salt in the atmosphere, but there is, instead, vapour, which plays as important a

[1] They at most, if not at all, seasons dip in a much lower latitude.
[2] Estimating the depth of the ocean as 2,500.

its circulation as salt does in that of the ocean. In conclusion, I would say, look at the isotherms between 65° 42′ S., and 50° 1′ S. published in Report No. 2 of the *Challenger*.

May 10 DIGBY MURRAY

ANCIENT GLACIERS IN AUVERGNE

HAVING just returned from Auvergne, where I have been searching for the tracks of former glaciers along the old volcanoes of the Monts Dome and Mont Dore, I send a few notes to NATURE, in the hope that they may prove useful to other geologists who may explore that most remarkable and interesting country during the ensuing summer. My companions were three members of the Cotteswold Naturalist's Field Club, Sir W. V. Guise (the President), Sir David Wedderburn, and Mr. Lucy, all well versed in the phenomena presented by glaciation.

With regard to the Monts Dome and the country round Clermont Ferrand, it is evident that no glaciers have occupied the vales since the outpouring of the later lava currents, and the volcanic outbursts of the craters of the Puys de Dome; and yet, as I have already mentioned in the pages of NATURE, M. Le Coq discovered remains of the Mammoth, Tichorhine rhinoceros, and Spermophilus, which had been washed into drifts and fissures in the most recent lava currents of Volvic and Gravenoire near Beaumont. Such drifts deserve *especial attention*, as they appear to owe their origin to a period when there was greater transportation of angular and subangular débris by rain-wash and melting snow, or neve, than there is at present. It may have been during this period that the northern animals became inhabitants of Central France. Such angular and sub-angular drifts may be seen in various localities as in the road which descends from the south side of Gergovia, between the village of Merdogne and the high road to Clermont Ferrand, and again at the base of the Puy Dallet, where the high road descends to the village of Dallet, and atmospheric drifts are seen to overlie the old river shingle of an ancient Allier. The geologist who examines the source of the old basaltic current which Mr. Scrope believes to have flowed from the Puy de Berzé, near St. Genest de Champanelle, and to have extended over the freshwater strata of Gergovia, may learn a good lesson as regards the deceitful appearances of glaciation often set up by granitic rocks. Most of the country between Ceyrat, near Mont Rognon, and Theix looks regularly "moutonéed," and may mislead anyone who has not become convinced, by careful examination, that this appearance is owing to atmospheric weathering, and the desquamation of the granitic rocks which separate at the joints and weather into rounded boulders assuming sometimes the aspect of blocs perchés. There are no signs of glaciation, however, among the older basalts which overlie the granite rocks, in so many localities, and which ought to show it if glaciation there had been.

In the country of the Monts Dore the evidence is most puzzling, and in some respects contradictory. Arrived at Monts Dore des Bains we searched carefully for glacier evidences in the valley of the Dordogne and the gorges de l'Enfer and de la Cour, and though some of the knolls are rounded, and there is a vast amount of débris from the rocks around and above, nowhere could we see signs of true moraines, perched blocks, or the usual evidences of glacier action; and certainly the position of the masses of rock called "Les Trois Diables," which I believe are by some set down as blocs perchés, are far too close to the rocks in situ to allow us to attribute their transportation to a glacier rather than to a fall from the precipices above. They belong to the "Chemins du Diable," which are preparing for a similar descent. Again, and I must here state that I arrived at conclusions contrary to those of my friends, I believe that a glacier has descended, in long ago ages, down the valley of the Dordogne, but so long since that the vast masses of débris which have fallen from the rocks which skirt the valley, combined with the wear and tear of atmospheric agencies, the constant shifting of the bed of the Dordogne and its hundreds of tributary rills which during the melting of the snows everywhere wash, roll, wear, and transport the débris of the vale, all have assisted in destroying and masking any glacier evidence there may have been in past times. I was led to this conclusion from the examination of the higher ground, and the detection of what I believe to be moraine matter and transported rock masses, on the road between Mont Dore des Bains and Latour, as on the platform below the Rochers de Beauzac, &c.

The Tranteine valley, where Dr. Hooker discovered the transported rock-masses and which he has already described in NATURE, lies at right angles to the Dordogne valley, runs due south, and faces the Cantal. It is difficult to understand why glacier relics should be preserved in this valley and none in that of the Dordogne. This difficulty, however, vanishes somewhat when surveying the difference in the contour of the ground, the difference in the watershed of streamlets, and the low hill against which the great rock-masses are stranded, consisting of moraine matter overlying beds of basaltic lava. The Tranteine valley may be reached by passing over the Col between the Pic de Sancy and Puy Ferrand, and turning down the gorge to the south, or by the long roundabout route through the village of Latour. We selected the former for our first attack, taking the Latour route two days later. I would here recommend as guide, Guillaume Pierre, of the Hotel Chabourg ainé, to whom I pointed out certain phenomena on descending the gorge, which I think are worthy of notice. I also recommend no one to attempt this route who is not a good walker—"Facilis descensus," &c. The transported rocks, one of which Dr. Hooker sketched, lie stranded in moraine matter, which again rests on beds of black basalt, as may be seen at the little waterfall of the Tranteine stream. The rocks themselves come from the Pic de Sancy, and consist of what Scrope calls "porphyritic trachyte," but perhaps now they may be termed a granitic felstone or a felstone porphyry. Dr. Hooker calls them domite, but this term is now usually applied to the white, light, pulverulent rock like that of the Puy Sarcoui in the Puys de Dome. On the right and left of the transported rocks the hills are rounded, and blocs perchés are seen resting on them. There is a fine section on the Tranteine stream, en route to Picherande, where large transported rock-masses may be seen resting on glacial till. Following the valley down to the bridge which crosses the Tranteine river between Latour and Picherande, the observer will find rounded surfaces and transported moraine matter, but a vast deal of atmospheric weathering has gone on since the days when the ice passed away.

Travelling down the valley of Besse to Lake Pavin, I thought I recognised glacier action; and again at the head of the valley of Chambon; but if glaciers ever flowed down these valleys, it is evident that they must have done so before the eruption of the Puy de Tartaret or the Puy d'Eraignes. The occurrence of the volcanic cone of Tartaret right in the middle of the valley of Chambon is fatal to the supposition that a glacier of any size ever came down from the mountains since the outburst of the cinders and lavas of Tartaret.

If, therefore, after three visits to the volcanic regions of Central France I may be permitted to give a broad view as to the time when glaciers swept down the valleys of Mont Dore, I should say that it was in days of old, when the Alpine glaciers reached the Jura, and the Rhine glacier swept over to the plains of Bavaria, when there were glaciers in the Vosges and in the Black Forest; and that when those ice rivers melted and passed away, so also did the glaciers of Mont Dore. W. S. SYMONDS

Pendock Rectory, Tewkesbury, June 5

NOTES

THE French Government has formally decided to accept the principle of obligatory primary instruction. M. Waddington proposes, moreover, to organise four great Universities in France, viz., at Paris, Lyons, Bordeaux, and Nancy, each of which will have an independent status. M. Waddington's legislation is entirely in accordance with the views which have been so frequently advocated in NATURE. The sooner that similar reforms are universally made the better it will be for the advance of solid education. The tendency, we are glad to think, to follow the German example, is spreading, and we hope it will soon reach our own country. Such institutions as Owens College, the Yorkshire College, and other similar bodies, cannot too soon spring into universities with the vigour of youth. The admirable vigour and promptness with which the French Government has carried out the much needed educational reform is in the highest degree hopeful.

ACCORDING to the photographs taken daily at Montmartre by M. Janssen, no spots have been now noticed on the sun since March 25. At the last meeting of the Paris Academy, M. Leverrier announced that in addition to the solar work to be carried on by M. Janssen in the new physical observatory of Paris, M. Cornu has been appointed to make corresponding researches in the National Observatory. It is extremely encouraging to witness astronomical research taken up with such vigour by France as well as by Germany.

WE regret to have to record the loss of one of the most indefatigable of our working naturalists in the death of Mr. Edward Newman, which took place on the 12th inst. at his residence at Peckham at the age of 75. Mr. Newman took up the study of natural history when a young man, as a relaxation from the labours of an active commercial life, and continued ardently devoted to it to the close of his life. He soon established himself as an authority in two branches especially, entomology and pteridology. His "Grammar of Entomology" was published as long ago as 1835; and his "British Ferns" still holds its place, notwithstanding a tendency to excessive species-splitting, as a standard manual of the ferns of these islands. He was the editor of the *Zoologist* and *Entomologist*, as well as of the *Phytologist*, which has ceased to appear for some years; and he was a large contributor to periodical literature, having had the control of the natural history department of the *Field*. Mr. Newman was a Fellow of the Linnean and Zoological Societies, and of several foreign academies, and has been president of the Entomological Society.

THE friends and admirers of the late Daniel Hanbury will be glad to learn that a selection from his papers and essays, with a memoir by Mr. Thomas Ince, F.L.S., is now in the press and will be ready for publication in a few days. The book will consist chiefly of papers on Pharmacology and Botany, and will be illustrated by a portrait engraved on steel and by a number of wood engravings and lithographs. Messrs. Macmillan and Co. are the publishers.

IN addition to the ordinary courses of lectures for science students at South Kensington this year, the Lords of the Committee of Council on Education are making arrangements for a course of sixty lectures on the scientific instruments in the Loan Collection. Their Lordships are in communication with the leading men of science in the country to enable them to carry out the important object they have in view.

ACCORDING to tidings which have been received at Berlin from the German expedition under Dr. Finsch, now exploring Western Siberia, it appears that the expedition left Tyumen on April 13, and proceeded to Omsk. From thence the explorers followed the course of the River Irtish across the steppes as far as Semipalatinsk, where the Russian Governor gave them a very hospitable reception. The travellers made their next halt at a Khirgiz *yourt*. From thence they were at the time of writing about to undertake an expedition into the mountains on the Chinese border. In the second half of the present month the explorers hoped to reach Bernaul, after which it was their intention to follow the course of the river Ob downwards. Dr. Finsch's letters are stated to contain some very instructive and interesting intelligence on animal and vegetable life in the regions traversed. The other expedition undertaken specially to explore the mouth of the river Ob started from Moscow on May 11. The two expeditions are to join at the mouth of the Ob and to return to Germany in company. They are expected back in the course of the autumn.

DR. W. PETERS has lately communicated to the Royal Academy of Sciences of Berlin a description of a very fine new species of wild sheep which is found in Eastern Mongolia, north of Pekin. Dr. O. von Moellendorff, of the Imperial German Legation at Pekin, has forwarded to the Zoological Museum of Berlin an adult male specimen of this animal, which Dr. Peters proposes to call *Ovis jubata*, from the long hairs which adorn its chest.

AT the meeting of the Zoological Society on Tuesday last, Mr. H. E. Dresser, F.Z.S., exhibited a series of specimens of a very fine new species of Snow Partridge, collected by Mr. C. G. Durnford in the Taurus Mountains, and described it under the name of *Tetraogallus tauricus*. This bird, which seems to be restricted to the Taurus range, where it inhabits the higher and more inaccessible mountains, is nearest allied to *Tetraogallus caspius*, but differs in being much larger, in having the upper parts much paler and washed with buff, the hinder portions of the neck and the fore-parts of the back ashy buff, almost unvermiculated, a broad pectoral band of ashy buff spotted with black; the flank feathers clear blue grey in the centre, with a chestnut stripe on each side, and an outside margin of black; and the lower breast, instead of being broadly marked with black, is ashy buff, finely vermiculated with blackish grey. This makes the fifth species of Snow Partridge now known to inhabit different parts of the Palæarctic region, the others being *T. caspius*, from the Caucasus, *T. himalayensis*, from the Himalayas, *T. altaicus*, from the Altai range, and *T. tibetanus*, from Thibet. Mr. Dresser also exhibited and described, under the name of *Limicola sibirica*, a new species of broad-billed Sand-piper from China, which differs from *L. platyrhyncha* in having the upper parts rich rufous, as in *Tringa minuta*, instead of deep blackish brown, as in the former species.

THERE are now living in the Zoological Society's Gardens, Regent's Park, four specimens of the Giant Tortoises of the Galapagos Archipelago, two having been brought home by the *Challenger*, and deposited by Prof. Wyville Thomson, and two by Commander W. E. de Cookson, of H.M.S. *Peterel*. They were all obtained from Albemarle Island, and are of the species known as *Testudo elephantopus*. These, together with the even larger specimens of *Testudo indica*, from Aldabra, form an unequalled series of living Giant Tortoises.

THE Very Rev. Principal Tulloch, D.D., Vice-Chancellor of the University of St. Andrews, was entertained at dinner on Monday night at St. James's Hall, by a large and influential gathering of the members of the St. Andrews Graduates' Association. Dr. Richardson, F.R.S., Assessor of the General Council in the University Court, presided, and was supported by the Earl of Elgin, Mr. Lyon Playfair, M.P., Dr. Lush, M.P., Sir Joseph Fayrer, K.C.S.I., and a large number of members of the asso-

ciation. The reception given to Principal Tulloch was enthusiastic. The Principal spoke of the past and present of the University with which he is connected. Sir Joseph Fayrer replied for the toast of the University of Edinburgh, and Mr. Danby Seymour eloquently proposed the health of the chairman. It is gratifying to find that this Scottish University is represented by so many eminent men of science in London; we would wish to see the example followed by other Universities.

UNDER the title of "Endowment of Research in America," the *Academy*, at President Gilman's request, gives publicity to the following circular: "The trustees of the Johns Hopkins University hereby offer to young men from any place ten fellowships, or graduate scholarships to be bestowed for excellence in any of the following subjects:—Philology, literature, history, ethics, and metaphysics, political science, mathematics, engineering, physics, chemistry, natural history. The object of this foundation is to give scholars of promise the opportunity to prosecute further studies, under favourable circumstances, and likewise to open a career for those who propose to follow the pursuit of literature or science. The University expects to be benefited by their presence and influence, and by their occasional services; from among the number it hopes to secure some of its permanent teachers.—*Conditions*: 1. The applications must be made in writing prior to June 1, 1876. The decision of the trustees, will, if possible, be made before July 1. 2. The candidates must give evidence of a liberal education (such as the diploma of a college of good repute); of decided proclivity towards a special line of study (such as an example of some scientific or literary work already performed); and of upright character (such as a testimonial from some instructor). 3. The value of each fellowship will be $500, payable in three sums, viz: $100, Oct 1; $200, Jan. 1; $200, June 1. In case of resignation, promotion, or other withdrawal from the fellowship, payments will be made for the time during which the office may have been actually held. 4 Every holder of a fellowship will be expected to render some services to the institution as an examiner, to give all his influence for the promotion of scholarship and good order—and in general to co-operate in upholding the efficiency of the University, as circumstances may suggest. 5. He will be expected to devote his time to the prosecution of special study (not professional), with the approval of the president, and before the close of the year, to give evidence of progress by the preparation of a thesis, the completion of a research, the delivery of a lecture, or by some other method. 6. He may give instruction, with the approval of the president, by lectures or otherwise, to persons connected with the University, but he may not engage in teaching elsewhere 7. He may be re-appointed at the end of the year. 8 These regulations are prescribed for the first year only." For further information inquiries may be addressed to D C. Gilman, president of the Johns Hopkins University.

Iron, on the authority of the Icelandic paper *Nordlingr*, states that two enterprising Icelanders, named Jow Thorkellsson and Sigindur Kraksson, have explored the volcanic region of the Dygyur Jelden. They started on their hazardous expedition from the Bardadal on Feb. 7, and in the course of their two days' exploration they succeeded, under great difficulties and dangers, in descending into the crater of the volcano Asya, where, at about 3,000 feet below the upper margin, they reached the bottom, and found themselves on the brink of a lake of seething hot water, which was apparently of great depth. Near the southern extremity of this lake the ground was broken up by fissures and pools, which prevented further progress in that direction, while the entire space resounded with the noise of loud subterranean thunder. North of the great crater the explorers found an opening about 600 feet wide, which appeared to be of about equal depth, from which issued dense masses of sulphurous smoke, accompanied by loud and deafening sounds.

THE Royal Society gave on Wednesday last week a *conversazione*, to which, for the first time, ladies were invited. The experiment was eminently successful.

THE members of the Birmingham Natural History and Microscopical Society propose to visit on Saturday next the Loan Collection of Scientific Apparatus, the South Kensington authorities having promised to afford them every facility. On the same day, under the guidance of Mr. W. R. Hughes, the members of the Society will visit the Crystal Palace Aquarium.

W. B. LOWE has been elected to a Foundation Scholarship at St. John's College, Cambridge, for proficiency in Natural Science. Houghton, Man, and Slater to Exhibitions.

AN examination will be held at Exeter College, Oxford, in October next, for the purpose of filling up a Natural Science Scholarship tenable for four years during residence, and of the annual value of 80*l*. There is no limit of age for this Scholarship. The examination will be in biology, chemistry, and physics.

THE Society of Geography of Paris, appointed some time since, a special committee on Commercial Geography. We learn from the *Explorateur* that this Committee is starting a new and independent Geographical Society. We have also received a prospectus announcing the formation of a Paris Society of Zoology.

THE Academy of Zurich has granted a doctorship in Medicine for the first time to a young lady, Miss Francisca Tiburtias, aged 23.

M. W. DE FONVIELLE has had a spectroscope constructed with a graduated screen permitting the quantity of light admitted to be diminished in a known ratio. The moving force being regulated at will, the radiometer can be put in a state of rotation under the rays of the most scorching sun and record taken of the motion very easily. With such an apparatus it was shown by comparison with a standard oil-lamp burning forty-two grammes an hour, that on June 9, at 4 o'clock precisely, the radiating force of the sun was equal to fourteen lamps at a distance of twenty-five centimetres from the axis of the radiometer. The apparatus is tried daily at La Villette gas-works, and results of the comparisons will be tabulated and discussed.

PROF. O. C. MARSH has discovered a new sub order of Pterosauria from the Upper Cretaceous of Western Kansas, North America, differing from the typical Pterodactyles in that no teeth were present in either jaw. The name given to the genus, *Pteranodon*, signifies this. The species was of large size, the skull of *Pteranodon longiceps* being thirty inches from the occipital crest to the end of the pre-maxilla. It must be remembered that the absence of teeth in a Pterodactyle *need* not lead to the inference that it is any way more nearly related to birds than the tooth-possessing species, because the character may have been acquired quite independently.

THE April number of the *Bulletin* of the French Geographical Society contains a memoir of the late Jules Duval, by M. E. Levasseur, an Account of a Journey in Herzegovina, by M. E. De Sainte-Marie, and Notices of the Basques, by Major V. Derrecagaix.

REINWALD AND CO., of Paris, have just added to their "Bibliotheque des Sciences Contemporaines" a work on Anthropology, by Dr. Paul Topinard, with a Preface by Prof. Paul Broca. Williams and Norgate are the English publishers.

In the *Monthly Notices* of the Royal Society of Tasmania for 1874 occur some interesting abstracts of papers read before the Society, including notices of the Angora goat, some species of Tasmanian birds, introduction of the salmon into Tasmanian waters, the Silurian fossils of Tasmania, the Tertiary basin of Launceston, and a list of the plants of Tasmania, prepared in 1875 by Baron Fred. von Mueller. To the notices are appended the meteorological observations made during the year by Mr. F. Abbott at Hobart Town, and by Mr. W. E. Shoobridge at New Norfolk. From the monthly notes we observe that meteorological observations are also made at Port Arthur, Mount Nelson, King's Island, and other places, and sent to the Society, but the results are not published, nor so far as we are aware have they been published since 1866. We hope the Society may soon be in a position not only to publish these results, but also results from a sufficient number of stations, so as to represent adequately the meteorology of the island.

The additions to the Zoological Society's Gardens during the past week include a Cariama (*Cariama cristata*) from South-east Brazil, presented by Capt. W. C. Chapman, H.M.S. *Dido*; two Black-eared Marmosets (*Hapale penicillata*) from Brazil, presented by Mr. G. Newton; a Rose-ringed Parakeet (*Palæornis docilis*) from West Africa, presented by Mrs. Haywood; a Hyacinthine Maccaw (*Ara hyacinthina*) from Brazil, presented by Mr. H. Wilson; a Moor Monkey (*Semnopithecus maurus*) from Java, a Bay Antelope (*Cephalophus dorsalis*) from West Africa, purchased; two Vulturine Guinea Fowl (*Numida vulturina*) from East Africa, a Puma (*Felis concolor*) from Central America, deposited.

SCIENTIFIC SERIALS

Poggendorff's Annalen der Physik und Chemie, No. 3.—According to the kinetic theory of gases, supposing the gaseous molecule to consist of only one atom, the relation of the two specific heats (as Clausius has shown), would be 1·666. The lower number obtained by experiment for several gases may probably be explained by the complex constitution of their molecules. It seemed desirable to MM. Kundt and Warburg to determine experimentally the specific heat of mercury vapour, which has been considered by chemists to consist of monatomic molecules. Their method was to produce a sound in two glass tubes placed end to end, and containing, the one mercury vapour, the other air. Having introduced powder into the tubes, they observed the distances between the nodes of vibration. Applying a formula of acoustics which comprehends, among other things, the densities, the temperatures, and the relation of the specific heats, and taking, as value of this relation in the case of air, the number 1·405, they obtain, for mercury vapour, the number 1·67, which may be considered as fully in accord with the number 1·666 furnished by theory.—In an interesting paper which follows, M. Colley, of Moscow, examines a particular case of work done by the galvanic current. Suppose a current to pass through a vertical column of some salt, *e.g.* nitrate of silver; both electrodes being in this case of silver. In a given time a certain quantity of silver is liberated and deposited. Now, if the current pass up the column, it lifts this silver against the force of gravity, and so does mechanical work, which, in the opposite case (of the current passing down) is not done. It appeared, then, as theory anticipated, that the downward current in such a column (as measured by the galvanometer), was stronger than the upward, and the difference was not greater than theory indicated. But both with a battery current and with that from a Clarke magneto-electric machine, it was considerably less. The author, seeking an explanation, regards as untenable the general views regarding passage of currents through liquid conductors, the phenomena of passage from the solid to the liquid conductor being generally ignored; and he thinks the facts favour Helmholtz's view, which regards the liquid, with the electrodes immersed in it, as a condenser of very great capacity. Weak currents which cannot pass through the liquid yet produce a polarisation of the electrodes (charge of the condenser). With strong currents the only difference is that as soon as the difference of tension has reached a certain limit (maximum of the electromotive force of polarisation), all newly arriving quantities of electricity can unite through the liquid. M. Colley shows how his results are deducible from the state of things thus supposed.—A number of experiments on electric clocks (with Tiede's pendulum) are described by Dr. Joseph Brunn.—Of the few remaining original papers we note one by M. Chwolson on the theory of interference-phenomena.—A good experiment for illustrating the explosive character of a mixture of oxygen and hydrogen gases is described by M. Rosenfeld.

Archives des Sciences Physiques et Naturelles, Jan. 15.—In the opening paper of this number M. de Candolle inquires into the causes of unequal distribution of rare plants on the Alpine chain (See NATURE, vol. xiii. p. 516).—M. Favre follows with a note on the glacial and post-glacial strata of the southern slope of the Alps, in the canton of Tessin and in Lombardy.—M. Pictet discusses the application of the mechanical theory of heat to the study of volatile liquids, and finds some simple relations between the latent heats, atomic weights, and tension of vapours.—A series of meteorological observations from the coast of Labrador, by Moravian missionaries, is communicated by M. Gautier (See NATURE, vol. xiii., p. 60).

SOCIETIES AND ACADEMIES

LONDON

Royal Society, May 18.—"On the Organisation of the Fossil Plants of the Coal-measures.—Part VIII. Ferns continued, and Gymnospermous Stems and Seeds." By Prof. W. C. Williamson, F.R.S., Professor of Natural History, Owens College, Manchester.

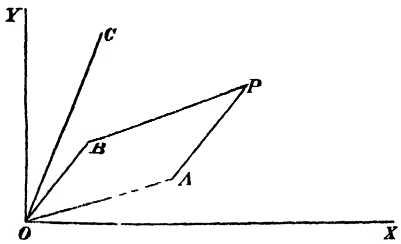
The author described the stem of a new fern, in which the principal vascular axis formed a cylinder enclosing a medulla, as in some Lepidodendra. This vascular cylinder gives off secondary bundles, to petioles, and rootlets, and each vessel is filled with tylose. Two kinds of Fern-sporangia were described—one Polypodiaceous, with a straight, vertical annulus; the other, with the annulus horizontal and subterminal, exhibits a type seen in the recent Schizeaceæ and Gleicheniaceæ. But the chief subjects of the memoir are the stems and seeds of Gymnosperms. Of the former various modifications of the *Sternbergian Dadoxylons* are described, and shown to correspond very nearly to many recent conifers, though with distinctive features of their own, especially in the structure of their woody fibres, and in the leaf-bundles of some species being given off in pairs. The author still excludes the Sigillariæ from the Gymnospermous group.

The most important novelties are the Gymnospermous seeds, exhibiting their internal organisation, found in France by M. Grand-Eury, and by the author in this country. Of these he describes a number of new genera and species in addition to the Trigonocarpous previously described by Mr. Binney and Dr. Hooker. The most remarkable of these is one designated *Lagenostoma ovoides*, in which a large flask-shaped cavity, inclosed within a crenulated canopy, occupies the apical end o the seed, between the apex of the endosperm and the exostome. Brongniart believed, with reason, that such cavities have originated in the absorption of the apex of the nucleus, leaving the corresponding part of the nucular membrane to form the cavity or "lagenostome." In this lagenostome large pollen-grains are found in many cases. Brongniart designates it the "Cavité pollinique." Examples of several other seeds presenting generic and specific modifications of the same type, as well as several species of the well-known genus Cardiocarpum and of Trigonocarpum. In all these the primary nucleus seems to have been absorbed, being now only represented by the investing nucular membrane. Within this is an inner structureless bag, which, in some of the Cardiocarpa, is filled with parenchyma, and which appears to represent the *secondary* perispermic membrane, or what is really the endospermic membrane, or *primary* embryosac of the Gymnosperms. The intimate structure of Trigonocarpum agrees with Dr. Hooker's description of it so far as the longitudinal sections are concerned, save that here, also, a "cavité pollinique" exists. Transverse sections show that the well-known sandstone casts of Trigonocarpum do not represent the external form of these fruits, but are *casts of the interior* of the hard endotesta. This latter was not trigonous externally, like the common specimens, but had twelve longitudinal ridges, three of which, corresponding with those of the sandstone casts, were more prominent than the rest. The endotesta was invested by a delicate parenchymatous sarcotesta. All these seeds appear to have Cycadean

rather than Coniferous affinities. One winged seed alone (Polypterospermum), from the uppermost coal-measures at Ardwick, resembles a true conifer. In conclusion, the author calls attention to the number of yet unknown stems and leaves of Phanerogams, which must have belonged to the numerous seeds now known to exist in the coal-measures of England, France, and North America.

Mathematical Society, June 8.—Prof. H. J. Smith, F.R.S., president, in the chair.—Mr. A. B. Kempe spoke on a general method of describing plane curves of the *n*th degree by link-work. He first described what he calls the *reversor* and the *multiplicator*. (These were first described by him in the "Messenger of Mathematics," vol. iv. pp. 122-3, in a paper "On some New Linkages.") He then explained the *additor* and the *translator*. Let $\phi(x, y) = 0$ be the equation to any plane curve of the *n*th degree, and let P be any point on the curve; construct the link-work parallelogram $OAPB$ in which

$$OA = BP = a,\ OB = AP = b,$$



and let the angle $AoX = \theta$, and the angle $BoX = \phi$, then—

$$x = a\cos\theta + b\cos\phi$$

$$y = a\cos\left(\theta - \frac{\pi}{2}\right) + b\cos\left(\phi - \frac{\pi}{2}\right)$$

Substitute these values of x and y in $\phi(x, y)$, expand and convert powers of cosines into cosines of multiple angles, and then the products of cosines into the cosines of the sums and differences of angles, we shall then get—

$$\phi(x, y) = \Sigma[A\cos(r\phi \pm S\theta \pm \alpha)] + C,$$

where r, s are positive integers, and $\alpha = \frac{\pi}{2}$ or 0 and A and C are constants. The author then proceeded to show how the constructions could be effected by his link-work, and he pointed out that his method would not be practically useful on account of the complexity of the link-work employed, a necessary consequence of the perfect generality of the demonstration. The method has, however, an interest as showing that there *is* a way of drawing any given case; and the variety of methods of expressing particular functions that have already been discovered renders it in the highest degree probable that in every case a simple method can be found. There is still, therefore, a wide field open to the artist to discover the simplest link-works that will describe particular curves. Mr. Kempe further pointed out that the extension of the demonstration to curves of double curvature and surfaces clearly involves no difficulty.—Mr. S Roberts then gave an account of a further note on the motion of a plane under certain conditions. (The former paper was read June 8, 1871).—Mr. J. J. Walker communicated a method of reducing the equation of a nodal plane cubic curve to its canonical form, in which the lines of reference are the nodal tangents and axis of inflexion.—Prof. Cayley described a surface connected with the sinusoid. Its edge of regression was given by the equations $x = r\cos\phi$, $y = r\sin\phi$, and $z = r\cos 2\phi$.—The president made a few remarks in connection with a recent note by M. Hermite, on a theorem of Eisenstein's.

Zoological Society, June 6.—Dr. A. Günther, F.R.S., vice-president, in the chair.—The Secretary exhibited some specimens of a Land-crab, from Ascension Island (*Geocarcinus lagostoma*), which had been presented to the Society by Dr. J. B. Drew, and read a note by Dr. Drew on their habits.—Mr. Sclater exhibited skins of a male and female of the new Pheasant from Borneo lately described by Mr. Sharpe as *Lobiophasis bulweri*. These birds had been obtained alive for the Zoological Society of Amsterdam, but the female only had lived to reach Amsterdam.—A letter was read from Mr. J. H. Gurney, containing some notes on the breeding of a pair of the Polish Swan (*Cygnus immutabilis* of Yarrell), and a description of the young birds.—A communication was read from Dr. Julius von Haast, F.R.S., containing some notes on the skeleton of *Ziphius Novæ Zealandiæ*.—A second communication from Dr. Julius von Haast, F.R.S., contained some notes on *Mesoplodon floweri*.—A communication was read from Dr. G. E. Dobson, containing a description of certain peculiarities in the structure of *Mystacina tuberculata*, which induced him to believe that this Bat used its feet for purposes of locomotion on branches and leaves of trees.—Mr. A. H. Garrod read the first part of a memoir on certain anatomical characters which bear upon the major divisions of the Passerine Birds.—A communication was read from Mr. E. L. Layard, C.M.G., containing notes on the Birds of the Navigators and Friendly Islands, with some additions to the ornithology of Fiji.—Mr. H. Adams and Mr. G. French-Angas communicated descriptions of five new species of Land Shells from Madagascar, New Guinea, Central Australia, and the Solomon Islands.

Royal Microscopical Society, June 7.—Mr. H. J. Slack in the chair.—A number of presents to the society were announced, including some rich diatomaceous earth from Santa Monica, near Los Angelos, sent by Mr. Hanks, of San Francisco.—A paper on a photograph of Nobert's bands, by Count Castracane, was read to the meeting and was supplemented by a short communication upon the same by Mr. H. C. Sorby.—Mr. Henry Davis gave an interesting account of some new observations which he had made upon *Chonochilus volvox*, and illustrated his remarks by drawings showing the principal features of the genus as distinguished from the Melicertians.—Mr. Chas. Stewart described and exhibited under microscopes in the room some minute spines found only round the pentagonal opening on the under side of the shell of the Echinoderms; he also gave a description of the remarkable structure of the large lachrymal gland of the common turtle, and exhibited preparations.

Victoria Institute, May 29.—Annual Meeting.—The Right Hon. the Earl of Shaftesbury, K.G., in the chair. The address was delivered by the Rev. Prof. Birks, of Cambridge. 115 members and associates have joined during the year, and the total number has risen to 690, two-thirds of whom are country and foreign members. The president, on behalf of the Institute, presented a testimonial to Capt. F. Petrie, who had acted as honorary secretary and editor of the "Transactions" for the last five years and a half.

BERLIN

German Chemical Society, May 22.—C. Scheibler, vice-president, in the chair.—A. Fischer described a modified water air-pump, remarkable for its cheapness. The brass instrument is sold by Messrs. Dreyer and Rosenkranz in Hanover for ten shillings, or with a manometer fixed to it for twenty shillings. It can be fixed to any laboratory table.—A. Horstmann confirmed observations by F. Isambert respecting the dissociation of the combination of ammonia with chloride of silver. For every degree of temperature a certain pressure can be observed, at which the separated bodies do not re-combine and the combination ceases to be decomposed. He also observed the existence of two compounds of the formulæ $AgCl.3NH_3$ and $2AgCl.3NH_3$.—A. Steiner has obtained the following combination of sulphuretted hydrogen with fulminic acid by passing H_2S into fulminate of mercury—

$$C_2H_2N_2O_2 + H_2S = C(NO_2)H_2 - CS.NH_2,$$

microscopical crystals, yielding, with a surplus of sulphuretted hydrogen, oxalic acid, sulphocyanide of ammonium, and sulphur—

$$2(C_2H_4N_2O_2S) + H_2S = 2CN_2H_4S + C_2H_2O_4 + S.$$

The same chemist by treating fulminurate of ammonium with sulphuric acid has obtained nitro-acetonitrile, $CH_2NO_2.CN$ (hitherto unknown), beautiful colourless crystals, fusing at 40°, burning with a brilliant flame. The substance is not identical with fulminic acid, because with mercury and silver it forms monobasic and not dibasic salts. He also described two bodies formed by the reaction of ammonia on fulminate of mercury, of the formulæ $C_6H_{11}N_9O_3$ and $C_7H_{13}N_{11}O_3$, guanidines, containing fulmi-guanurates. At the end, double salts of fulminate of mercury with sulphocyanide of potassium and ammonium, and also with cyanide of potassium were described.—E. Demole published researches on a body lately described by Baumstark, C_4H_9IO, under the name of ethylidene-iodo-oxethyl. Mr. Demole's researches lead him to suppose that this body is derived from ethylene and not from ethylidene.—A.

Laubenheimer has found nitro-meta-chloro-nitrobenzol to exist in four modifications, chemically identical but differing in physical and crystallographical respects. The same chemist has transformed the above-named substance by boiling it with an alcoholic solution of potash into nitro-chloro-phenol and mono-chloro-chinone, $C_6H_3ClO_2$; and by treating it with aniline into chloro-nitro-diphenylamine, $C_6H_3Cl(NO_2) . NH . C_6H_5$. Nascent hydrogen transforms dinitrochlorobenzol into chlorinated phenylen-diamine.—L. Mears has studied the action of nitric acid on benzanilide, which yields three isomeric nitro-benzanilides.—W. Grethen has transformed acetanilide into ortho- and para-nitro-acetanilides, formed simultaneously.—C. Sennewald described meta-amido-benzanilide. The same chemist has transformed anhydro-benzoyl-diamidobenzol—

$$C_6H_4 . N . C . C_6H_5 . NH,$$

into the amylic substitution-compound—

$$C_6H_4 . N . C . C_6H_5 . N . C_5H_{11},$$

and into the corresponding ethyl-compound.—H. Hübner and F. Frerichs have studied the action of iodide of cyanogen on diamidobenzoles. The result is expressed by the equation—

$$2C_6H_4(NH_2)_2 + CNI = C_{13}H_{12}N_4 = C_6H_4(NH_2)N - C - N(NH_2)C_6H_4.$$

—O. Hesse reported on the properties of a new alkaloid called cusconin.—Th. Collen described the action of sulphuric anhydride on para-chlorobenzoic acid, resulting in the formation of a mono-sulphonic acid, $C_6H_4Cl(COOH)(SO_3H)$.—C. Liebermann has observed the formation of rosolic acid when phenol is treated with chloroform and sulphuric acid. This explains the ordinary formation of rosolic acid by heating phenol with oxalic acid.

STOCKHOLM

Academy of Sciences, April 12.—Dr. G. Lindström of Wisby was chosen Intendent of the Palæontological department of the Riks Museum. The following papers were communicated:—On the amplitude of the daily variation of temperature in Sweden, by Herr Rubenson.—On the varieties of Diabase and Gabbro in Sweden, by Herr A. E. Törnebohm.—Recherches sur un nouveau genre des Holothuries, by Docent Hj. Theel.—Contributions to a monograph of the Amphipoda, I.—The family Oxycephalidæ Spence Bate, by Docent C. Bovallius (this paper is written in English).—The land and fresh-water mollusca of Siberia, I., by Dr. Westerlund.—On the Dannemora iron-ore field, by Engineer A. E. Fahlcrantz.—Notes on the vertebrate fauna of North Bohus lan, by Herr C. Cederstrom.—Primæ linæ muscorum cognoscendorum, qui ad Caldas Brasiliæ sunt collecti, by J. Angstrom, M.D.—Herr Santesson was chosen president for the year now commenced. The retiring president, Herr Wœrn, gave an address on the manufacture of iron and steel in North America.

PARIS

Academy of Sciences, June 5.—Vice-Admiral Paris in the chair.—The following papers were read:—Astronomical researches (continued) by M. Le Verrier. He presented vol. xii. of the *Annales de l'Observatoire*, containing the tables of Jupiter and Saturn.—On the thermal formation of ozone, by M. Berthelot. He passed a current of oxygen through a tube, where it was acted on by the silent electric discharge, into a phial containing dilute arsenious acid. The transformation of the acid into arsenic acid was noted, and the heat liberated compared with that liberated in oxidation of arsenious acid by free oxygen. The heat liberated by change of ozone into ordinary oxygen is thus found to be + 14·8 cal., that is, − 14·8 in formation of ozone (or − 29·6 per atom). Ozone is thus a body formed with absorption of heat.—On the absorption of free nitrogen by organic matters at the ordinary temperature, by M. Berthelot. This occurs under influence of the silent discharge, and is well marked in the case of benzine; marsh-gas, acetylene, &c., also show it. Such phenomena must occur in thunder-storms, and have important physiological effects.—On the origin of organised ferments, by M. Pasteur. He controverts M. Frémy's results.—Influence of age of a tree on the average time of opening of its buds, by M. De Candolle. In certain species (horse-chestnut, *e.g.*) age has no influence; whereas, in others (such as the vine), it acts sometimes by retarding, sometimes by accelerating, the epoch in question.—On the displacement of lines in the spectra of stars, produced by their motion in space, by Mr. Huggins.—Examination of the possible mechanical action of light; study of Mr. Crookes's radioscope, by M. Ledieu (continued). He describes the experiments made by M. Fizeau, at his suggestion, with polarised light (the results were negative), proposes new experiments, and applies his theory in explanation of some celestial phenomena.—On the formation of an international committee for scientific exploration of the American isthmus with a view to making a canal, by M. de Lesseps.—M. Cosson presented a small apparatus called a central inflammatory obturator (for cartridges.)—Report on several memoirs of M. Allard on transparence of flames and of the atmosphere, and the visibility of lighthouses with flashing lights.—On the relations between the theory of numbers and the integral calculus, by M. Lucas.—On the photographic images obtained at the focus of astronomical telescopes, by M. Angot.—On the law of Dulong and Petit, by M. Terreil. He interprets it purely with reference to the laws of chemistry. The specific heat of bodies doubles when they cease to be gaseous.—On the irrigations in the south of France, and particularly in the department of the Bouches-du-Rhône, by M. Barral.—On the duration of tactile sensation, by M. Lalanne. Suppose a flexible body which will not hurt the skin by motion in contact with it, to be rapidly moved round the arm or leg. Analogously to the impression of a luminous circle before the eye when an incandescent stick is whirled rapidly, a continuous sensation should at a certain speed be produced, like that from pressure of a bracelet or ring. This is never experienced with less than ten turns per second. The least duration of tactile sensation observed was $\frac{1}{24}$ to $\frac{1}{35}$ of a second. It varies with individuals, and in different parts of the body.—On the galls of leaves of French vines, &c., by M. Boiteau. Notes on history of Phylloxera, especially the species *Phylloxera Acanthochermes*, Kollar, by M. Lichtenstein.—Memoir on the perturbing influence of neighbouring masses, on the form and disposition of crystals, by M. Brame.—On linear equations of the second order, by M. Pepin.—On the development in series of the functions Al(x), by M. Foubert.—On the number of points of contact of algebraic or transcendent curves of a system with an algebraic curve, by M. Fouret.—Improvement in Watts's indicator, by M. Mallet.—On the inconveniences arising from use of a cable of copper wire as conductor of a lightning-rod, by M. Francisque Michel. Such wires under electric action show, ere long, a series of fractures, which lessen considerably the conducting section.—On the influence of certain salts and of lime on saccharimetric observations, by M. Muntz.—On a derivative of acetylacetic ether, oxypyrotartaric acid, by M. Demarçay.—Combustion of organic matters under the double influence of heat and of a current of oxygen, by M. Loiseau.—Metallisation of organic substances, fitting them to receive galvanic deposits, by M. Cazeneuve.—Action of digitalis compared with that of biliary salts on the pulse, arterial tension, respiration, and temperature, by MM. Feltz and Ritter.—On the vascular apparatus of Trematoda, by M. Villot.

GOVERNMENT AID TO SCIENTIFIC RESEARCH

WE publish below a correspondence which we cannot but regard with the greatest satisfaction; Government has at last seen it to be its duty to act upon the recommendation of the Duke of Devonshire's Commission, and make a substantial contribution towards the endowment of pure scientific research. We need scarcely remind our readers that from the first we have maintained that such endowment is the duty and interest of civilised states. But indeed it is long since the British Government practically acknowledged this to be the case; the grant of 1,000*l.* yearly to the Royal Society for purposes of research was first made twenty-five years ago. We hope the additional ...*l.*, making up 5,000*l.*, will be put to such excellent use that Government will not only renew the grant at the end of the five years, but see the necessity of increasing it to at least the sum suggested when the 1,000*l.* was first granted. No doubt the first to bring the duty of the State in respect to science prominently before the public in this country was the late Colonel Strange. He broached his scheme many years ago at the Norwich meeting of the British Association, and by his earnest and untiring advocacy he soon gained to his views most of the scientific men of the country, and Government became so impressed with the importance of the subject that the Science Commission was appointed in 1870. The substance of the various Reports of this Commission is familiar to our readers; the mass of evidence it has elicited has probably done more than anything else to enlighten the country and our Government as to the high importance and wide extent of scientific research. We can hardly expect Government to carry out all at once the recommendations of the Commissioners as to the extent to which unremunerative research should be assisted; but no doubt the 4,000*l.* which is to be annually entrusted to the administration of the Royal Society for the next five years, is the first, partly tentative step towards this. Then there were the strong words of Lord Derby, at Edinburgh, last December (see NATURE, vol. xiii. p. 141): "I think," he said, "that more liberal assistance in the prosecution of original scientific research is one of the recognised wants of our time." As the natural outcome of all this, and no doubt mainly as the result of the recommendations of the Science Commission, the Government has resolved to try what good results are likely to follow from a first and moderate endowment. We think we may safely prophecy that the result is likely in time to lead to the increase of the grant to at least the sum proposed to be entrusted to the Royal Society twenty-five years ago.

The difference between this new grant of 4,000*l.* and that of the old 1,000*l.*, should be noted. In the case of the latter the money had to be expended on instruments, &c., by the recipients, whereas in the case of the new grant the endowment may be personal; the grants may be made to individuals not merely to provide themselves with apparatus, but as a means of sustenance while prosecuting scientific researches incompatible with the pursuit of an ordinary means of livelihood. And here we should remark that we never advocated in these columns the wholesale selection of untried youths for the receipt of such endowments, nor is it meant thus to allocate the grant which has been made. The selection will be made from among those who by the work which they have already done have proved themselves capable of making a profitable use of the endowment.

Another point in the conditions attending the new grant we notice with pleasure, namely, the reconstruction of the Government Grant Committee of the Royal Society, so as to include the Presidents of the principal Scotch and Irish Societies, as well as those of the chief London scientific bodies. Thus the interests of Scotland and Ireland are as well cared for in this matter as those of England.

The Royal Society has now a great responsibility resting upon it. What with the annual 4,000*l.* from Government, in addition to the previous 1,000*l.*, and the 6,000*l.* which Mr. Jodrell has entrusted to its administration, it will have critical and important duties to science and to the country to perform. We are sure it will take every care so to allot these funds as to prove that it has only the interests of pure science at heart, and is quite competent to carry out the intentions of Government as well as of private donors.

The following is the correspondence in relation to the grant which has passed between Government and the Royal Society:—

LETTER TO THE PRESIDENT OF THE ROYAL SOCIETY.

Science and Art Department, South Kensington, S.W., April 29, 1876

SIR,—Her Majesty's Government have had under their consideration the question of giving some further aid to scientific research.

As you are aware a sum of 1,000*l.* is voted annually by Parliament "to enable the Royal Society to defray the expenses of scientific investigations considered by a Committee of the Society to be worthy of such aid." This Committee, called the Government Grant Committee, consists of the President and Council of the Royal Society and twenty-one other gentlemen of scientific eminence not members of the Council; and the Grant is expended in aiding investigators to provide themselves with apparatus and assistants, but never in personal payments to the investigators themselves.

It is proposed that this action of the State should be extended, and that further aid should be given to research by according permission to the Government Grant Committee to recommend in certain cases the payment of personal allowances to gentlemen during the time they are engaged in their investigations; that a sum of 5,000*l.*, including the above-mentioned 1,000*l.*, should be taken annually; that the Royal Society should be invited to aid Her Majesty's Government with their advice and assistance in its appropriation and expenditure, and as to the sums to be granted in each case, reporting annually to the Lords of the Committee of Council on Education on the progress made and the desirability or non-desirability of renewing the grant; and that this experiment should be tried for five years.

The Administration and expenditure of the grant, and accountability for it, should we consider be vested in the Science and Art Department of the Committee of Council on Education by which the vote will be taken; and all instruments purchased for investigations should be left in its charge when no longer required.

It would be advisable that the Presidents of the following Societies should be ex-officio members of the Government Grant Committee, viz. :—

The Royal Society of Edinburgh,
Royal Irish Academy,
Royal Astronomical Society,
Mathematical Society,
Chemical Society,
Linnean Society,
Zoological Society,
Geological Society,
Physical Society,
Institution of Civil Engineers,
Institute of Mechanical Engineers,
General Council of Medical Education and Registration of the United Kingdom.
Royal College of Physicians,
Royal College of Surgeons, and
British Association.

No definite rule can be laid down as to the amounts to be awarded in individual cases. These must depend upon various circumstances, especially on the amount of time which the investigator devotes to the inquiry.

There would be no objection to the application of some portion of this fund to the payment of such clerical assistance as may be found necessary.

I should feel obliged if you will consult the Council of the Royal Society on this scheme and inform me what is their opinion of it, and also give me the benefit of any suggestions as to modifications that may occur to them or to you.

I have the honour to remain, Sir,
Your obedient servant.
(Signed) RICHMOND AND GORDON

LETTER TO THE PRESIDENT OF THE ROYAL SOCIETY.

Science and Art Department, South Kensington, S.W., May 29, 1876

SIR,—In reference to our conversation on Monday last on the subject of the Duke of Richmond and Gordon's letter of April 29, I should feel obliged by your informing the Council of the Royal Society that the Lords of the Committee of Council on Education agree with you in thinking that, under the circumstances, it would perhaps be more advisable to leave the grant of 1,000*l.* exactly as at present. The conditions of the Lord President's letter would then apply only to the vote of 4,000*l.* Should the Council of the Royal Society concur in this view, we will communicate with the Treasury on the subject. The recommendations of the Royal Society with respect to the appropriation of the 4,000*l.* must, no doubt, be liable to revision by the Minister responsible to Parliament for its due administration, and of this responsibility he cannot divest himself. But the power is one, we believe, for the exercise of which there is never likely to be occasion. Should it, however, happen that the Committee of Council on Education found it inadvisable to act on all of the recommendations of the Royal Society, the best
course would probably be to give the Council an oppor-
items of revising them ; so that, if thought desirable, the
might be the grant, to which exception had been taken,
Society are llocated in some other way. If the Royal
or rejected as 'll desirous that the grant should be accepted
Council on Educwhole, the Lords of the Committee of
shall be done. But on will of course undertake that this
Council will agree thaty believe on consideration that the
have a mischievous effecch a course would be likely to
those recipients of grants wnnd entail great hardship on
attended their investigations, from the success that had
pected the continuance of their might naturally have ex-
As respects the reports of programts.
that the Council of the Royal Societys, My Lords believe
ment will naturally desire to have laid wellsee that Parlia-
them such a
report from those capable of giving an opinion, as will enable them to judge of the nature and amount of work being done, and the desirability, or otherwise, of continuing the grants. It is not asked that the report should be in any great detail ; as a rule it would be sufficient if it were of a general character, unless some of the subjects should from their special nature seem to require more precise information. The Lords of the Committee of Council on Education are fully aware of the great difficulties which surround the question of the direct encouragement of research and of the labour and responsibility that must necessarily be entailed on those who undertake to organise the experiment in this country. They therefore are glad to find that they may reckon on the cordial co-operation of the Royal Society, to whom they naturally first appealed to aid them in this matter.

I have the honour to be, Sir,
Your obedient Servant,
(Signed) SANDON

J. D. Hooker, Esq., C.B., M.D., &c.,
President of the Royal Society

LETTER TO LORD SANDON.

The Royal Society, Burlington House, W., June 2, 1876

My Lord,—With reference to your Lordship's letter to the President of the Royal Society dated May 29, I am to inform you that the President and Council of the Royal Society concur in the proposal therein contained, namely that, while the grant of 1,000*l.* should remain exactly as at present, a vote of 4,000*l.* should be taken on the conditions expressed in the Lord President's letter ; and that, in case it should happen that the Committee of Council on Education found it inadvisible to act on all the recommendations of the Royal Society, the Council of the Royal Society should have an opportunity of revising them, so that, if thought desirable, the items of the grant to which exception had been taken might be allocated in some other way.

I have the honour to be, my Lord,
Your obedient Servant,
(Signed) G. G. STOKES, Secretary, R.S.

The Lord Sandon, &c., &c., &c.

WALLACE'S GEOGRAPHICAL DISTRIBUTION OF ANIMALS[1]

The Geographical Distribution of Animals, with a Study of the Living and Extinct Faunas, as Elucidating the Past Changes of the Earth's Surface. By Alfred Russel Wallace. Two Vols. 8vo. (London : Macmillan and Co., 1876.)

II.

THE second part of his great work on Geographical Distribution Mr. Wallace devotes to the discussion of fossil animals. It might seem at first sight, as our author observes, rather out of place to begin the systematic treatment of this subject with extinct animals rather than with recent ones. But those who take the trouble to read these most interesting chapters will be speedily convinced to the contrary. Imperfect as is our knowledge of the geological past, enough has been already ascertained to enable some enchanting theories to be started which account to a greater or less extent for some of the most difficult problems of the present. As regards the comparatively recent extirpation of large and important forms which has taken place in Europe, in North America, and in South America alike since Post-Pliocene times, "it is clear," our author tells

[1] Continued from p. 168.

us, "that we are now in an altogether exceptional period of the earth's history," some idea of which it is very necessary to realise. "We live in an impoverished world, from which all the hugest and fiercest and strangest forms have recently disappeared." The cause of this great change over such a large part of the world's surface was, in Mr. Wallace's opinion, the "glacial epoch," which, according to Mr. Belt's theory, heaped up most of the water in the earth in mountains of ice round the two poles and left the great ocean beds comparatively dry. This, we are told, "must have acted in various ways to have produced alterations of the levels of the ocean as well as vast local flows, which would have combined with the excessive cold to destroy animal life" We are not sure that this is a *very* satisfactory explanation of the simultaneous disappearance of the great Irish Elk from Europe and the *Megatherium* from South America, but it is at all events *some* explanation of an obscure point, and deserves careful consideration So also do those few cases in which geological evidence is already sufficient to give us indications of the original birth-place of some of the mammalian types, and of the mode in which has come about their present state of distribution

The third section of Mr Wallace's great work, which we now enter upon, is, in fact, the most important of the whole, and that to which the previous chapters may be regarded purely as introductory Having shown us what the six great divisions of the earth's land-surface, zoologically considered, are, and how it may have come to pass that they are what they are, Mr. Wallace takes them one after the other in order, and gives us a separate memoir upon each of them, and their special zoological

FIG 3—A Brazilian Forest, with characteristic Mammalia

characteristics After a description of their territorial outlines, illustrated by hypsometrical maps in which the boundaries of the sub-regions are likewise indicated, general remarks are given upon their leading zoological features. The chief forms of mammals, birds, reptiles, batrachians, fishes, butterflies, beetles, and land-shells, which characterise them are pointed out. The Sub-regions into which they are divisible are then taken up and treated in greater detail, and the leading authorities from whose labours the necessary facts have become known to us are cited. At the end of each memoir "tables of distribution" are added, in which are given—first, a list of the families of the selected groups of animals represented within the Region, with an indication of their range, if any, beyond the Region, and secondly, a similar list of the genera of the terrestrial mammals and birds, with an indication of their ranges both within and beyond the Region Three or four plates, drawn by the late Mr J B. Zwecker, accompany each memoir.

These are intended to illustrate the physical aspect and zoological character of some well marked division of the region, and as only such species are figured as "do actually occur together in a state of nature," the scenes represented are "at all events not altogether impossible ones," which is more than many of our artistic friends can say of *their* productions! While we could have wished that Mr. Zwecker had resorted in some cases to the Zoological Society's Gardens rather than to previously published figures for the models of some of his animals, we must acknowledge generally the truthfulness of these illustrations and the faithful manner in which they have been executed At home alike in the tropics of the Oriental

and of the Neotropical regions, no one surely could have been more competent than Mr. Wallace to select the most characteristic forms for these plates, and we have great pleasure in reproducing some of them in these columns.

To those who know anything of Natural History the enormous labour involved in the compilation of these six memoirs will be at once apparent. The mass of details to be gone through in bringing together the most prominent known facts connected with the mammals, birds, reptiles, amphibians, fishes, butterflies, beetles, and land-shells of every different part of the world's surface, is a task that the boldest naturalist might well stand aghast at, especially when it is recollected that these details have to be picked out from several hundred different works and periodicals published in every quarter of the globe. That errors can be escaped in such a compilation even by a writer so cautious and so competent as Mr. Wallace is manifestly impossible. No intellect could expect to obtain personal acquaintance with more than a few selected branches of such a multifarious subject, and for the rest an author must trust to second-hand information. The selection of such second-hand information and its reduction into a uniform shape, is of itself a task of appalling magnitude, and we can only congratulate Mr. Wallace on having had strength and leisure to accomplish such a Herculean labour.

The fourth and last part of Mr. Wallace's work contains, as we have already explained, a review of the distribution of the different groups of animals which he has selected for the illustration of geographical distribution arranged in systematic order. The families are taken up

FIG. 4.—A Forest Scene on the Upper Amazon, with some Characteristic Birds.

one after another, the principal genera are mentioned, and notes are given on the more remarkable species. At the end of each order is appended a series of remarks on the general distribution of the whole group. This is in fact the storehouse of information from which the essays on the six zoological regions have been compiled, and should in strictness have preceded the third section of the work instead of following it. The author wisely recommends persons not well versed in zoology to read the more important parts of it—especially the observations at the close of each order—before they begin Part III. As regards this systematic treatise the observations which we have already made on the difficulties to be mastered in the compilation of the memoirs relating to the six geographical regions are still more applicable. It would be easy to point out many passages in which Mr. Wallace has not in our opinion made the most judicious choice of authorities. Errors of detail are, however, as has been already stated, unavoidable in a work of this extent—happy is he who makes fewest of them! Even in the case of some of the largest and most prominent families of the great class of mammals, naturalists are by no means yet agreed as to the number of species and genera that should be admitted. For example, Mr. Wallace, we observe, assigns "four, or perhaps five" rhinoceroses to Africa, but Prof. Flower—one of the highest living authorities on this class of animals, in a recent paper read before the Zoological Society of London—could only recognise *two*. Mr. Wallace admits the validity of *Elasmognathus* of

Gill as a genus of Tapirs, and adopts Dr. Gray's multitudinous division of the well-defined and eminently natural group of Eared Seals (*Otaria*). Many naturalists would hesitate before following Mr. Gill and Dr. Gray as authorities on these (or perhaps we may add on many other) subjects. But such and similar errors on questions of detail do not, we believe, affect the validity of Mr. Wallace's general conclusions. After the miserable stuff usually thrust before us in even the best and most recent treatises on geography, when the question of distribution comes to be touched upon, it is truly refreshing to turn to Mr. Wallace's broad and enlightened views on this subject. Future compilers of geographical manuals will have an easy task when they come to this most important but hitherto most ill-used part of their work, if they will only cast aside all that they have previously written, and borrow freely from the volume now before us.

Mr. Wallace has already registered many claims on the gratitude of naturalists present and future. In their interest he has explored the tropics of the east and the wildernesses of the west, and has brought home numberless novelties. He has written one of the best and most instructive books of naturalists' travels ever yet issued. He was, as is well known, the joint inventor with Mr. Darwin of the theory of "Natural Selection." But beyond all these scientific feats—and they are no mean ones—he has accomplished a task that will extend his fame even more widely amongst those who love science, as the author of the first sound treatise on zoological geography.

TWINING'S "SCIENCE MADE EASY"

Science Made Easy: a Series of Familiar Lectures on the Elements of Scientific Knowledge most Required in Daily Life. By Thomas Twining. (London: Chapman and Hall, 1876.)

THESE thin clearly printed quartos represent a remarkable experiment; an attempt to diffuse good teaching without good teachers, and to reproduce first-rate popular lectures without the need of multiplying skilled lecturers to deliver them. The author, Mr. Twining, constructed in 1856 an Economic Museum at Twickenham, which exhibited illustrations of scientific knowledge as applicable to the concerns of daily life. After fifteen years of continuous improvement this collection was destroyed by fire; but the experience gained in working it strongly impressed upon its author the conviction that the level of popular culture in this country is below the point at which intelligent appreciation of the simplest scientific object becomes possible; since his fine museum, with its methodical classification, its careful explanatory labelling, and the oral instruction of its active curator, failed to convey knowledge to the mass of visitors, to whom the very alphabet of science was unknown, and whose minds were untrained to the reception of the simplest truths. It is a bold thing for one man to enter on the task of educating a people; but Mr. Twining's enthusiasm was equal to the attempt. Precluded himself from lecturing, he prepared carefully-written lectures, founded on his Twickenham experience, and entrusted them to others to deliver. The swimming bath of East Lambeth, dry and unused in the winter, was fitted up as a lecture-room, and a course of five lectures was there delivered to attentive audiences of more than a thousand persons. Demands for their repetition arose from all parts of London; and during the last nine seasons they have been delivered in various mission-rooms, institutes, and clubs of the working-classes to crowded and eager hearers. Uneducated learners, however respectfully attentive, yet carrying away from a lecture ideas crude and disjointed, may lapse within a few days into their original ignorance; Mr. Twining therefore began early to test his audiences by a system of examinations, so modified as to meet the inexperience of candidates and the elementary character of the teaching. Examination programmes were issued, containing a full set of possible questions on the course, from ten to fourteen being allotted to each lecture, with the understanding that from every one of these groups two questions would be selected by the examiner; while a preliminary examination "of a friendly kind" struck off all who were clearly incapable of presenting themselves with any prospect of success. Under these limitations we are told that a large number of candidates have obtained prizes and certificates at successive examinations, their papers showing that they had grasped and could reproduce intelligently a fair amount of the teaching which they had received.

Mr. Twining thinks that what has been done in London may easily be done elsewhere; he therefore prints his lectures, and prefaces them with minute instructions for the guidance of such amateurs as may wish to organise and carry out the course. In its delivery two persons are necessary, a "reader" and a "demonstrator." The reader must be a good elocutionist, and need be nothing more; need know nothing of science in general, nothing of the particular science on which he is discoursing. If he is clever enough to introduce here and there a happy local *à propos*, so much the better; but he is a mere vehicle for the transmission of the matter contained in his text, and is not required to do more than utter it. The demonstrator must know something of science, and have some practice in manipulation; but the simplicity of the experiments and the fulness of the printed directions reduce this necessity to a minimum, so that the author proposes to himself as suitable interpreters in a country town the national schoolmaster as reader, and the doctor or dispensing chemist as demonstrator. Reference numbers, dotted lines, and other devices, indicate the relative duties of the two performers, who cannot of course expect to work smoothly and in concert without repeated and laborious rehearsals.

The ordinary science teacher, luxuriating in abundant time, in ample apparatus, and in educated hearers, might be tempted to speak unfavourably of the lectures themselves, as too condensed for practical usefulness. He might say, and say truly, that the matter contained in the three lectures on Mechanical Physics could scarcely, by a master teaching boys, be included in the five-and-twenty lectures of an ordinary school term; that the two lectures on Chemistry are overgrown object lessons; that no one of the seventeen topics treated in the single lecture on Chemical Physics would demand less than an hour's careful teaching in a class-room; and that the "questionary," or examination programme, represents pure and simple cram. But such criticism would be wholly unfair applied to Mr. Twining's enterprise, as overlooking its

condition and its aim: the condition, an audience of weary working-men, with little time to give, and who reject all instruction which is not easily grasped and enlivened by amusing spectacles: the aim, to communicate entertaining knowledge in a utilitarian spirit, to open a glimpse of intellectual enjoyment such as may at the same time bear practically on the comfort and happiness of daily life. In the experience necessary for such a taste Mr. Twining probably stands alone, and in reviewing the forms his efforts have taken we may fairly bow to the judgment which shaped them.

But the main objection to this curious and novel system will occur to everyone. Is it possible that any man uttering the knowledge and the thoughts of others on a subject with which he is quite unfamiliar can import into his task the enthusiasm necessary to kindle and inform an audience? A purchased sermon read from a pulpit never yet edified anyone; will it be more inspiring to receive scientific truth from the lips of a man who articulates by rote instead of teaching from that lofty standpoint of superior knowledge which converts hearers into disciples? Mr. Twining speaks gratefully of the admirable readers he has been fortunate enough to find in London. They were probably not mere elocutionists, but possessed of dramatic minds, and able to generate at will enthusiasm in a noble though unfamiliar subject, and their like will not be met with every day. Mr. Twining shows his uneasiness on this point by his strong injunctions to careful practice on the part both of reader and demonstrator, and whoever attempts to carry out the scheme will have to lay special stress on this. Nor can we omit to mention the subject of expense. The apparatus necessary *only* for the six lectures before us costs, exclusive of plans and diagrams, from 44*l.* to 48*l.* 10*s.* A club, society, or institute, including dexterous workmen amongst its members, could probably obtain all that is wanted at half this price, but in many places the difficulty of meeting the expense might turn the scale against the introduction of the lectures.

These difficulties have, no doubt, been well considered by the author of the scheme, and are thought by him to be not insurmountable. We most sincerely hope that it may be found so. His enterprise will be watched with no slight interest by all who feel that the spread of scientific knowledge among the operative classes is a pressing national necessity, and that one who devotes to it, as Mr. Twining has done, experience, thought, and toil, deserves the gratitude and the help of his countrymen.

W. T.

OUR BOOK SHELF

Life with the Hamran Arabs. An account of a Sporting Tour of some Officers of the Guards in the Soudan during the winter of 1874-5. By Arthur R. Myers, Surgeon, Coldstream Guards. With Photographs. (London: Smith, Elder, and Co., 1876.)

THE sporting tour of which Mr. Myers gives the narrative in this volume was made at the same time as that described by the Earl of Mayo in the work which we recently noticed. Indeed the two parties started together, and their work lay in regions not far distant from each other. Mr. Myers and his party were much more fortunate than the Earl's party. They did not meet with so many hindrances, and were much more fortunate in the number and variety of animals that came in the way of their rifles. The region to which Mr. Myers's work refers is on the borders of Abyssinia and Egypt, and has been already made familiar to English readers by Sir Samuel Baker in his "Nile Tributaries." Mr. Myers simply pretends to tell of his sporting adventures, and therefore we have no reason to complain if he adds little to our knowledge of the country of the Hamran Arabs. He writes in an unpretentious style, and his work will be found interesting by the general reader, and specially so by those who love sport. It contains photographs of some of the trophies brought home, arranged by Ward and Co.; they give a good idea of the variety of animal life to be met with in this part of the Soudan.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

The Decrease of the Polynesians [1]

I BELIEVE there are some errors popularly received respecting the rapidity with which the inhabitants of Polynesia, as a whole, are disappearing before an advancing civilisation. I wish to make a few statements on this subject in connection with a review of Miss Bird's book on "The Hawaiian Archipelago," which appeared in NATURE, vol. xi. p. 322.

The primary source of error is the excessively high estimates as to the population of different islands in Polynesia made by early visitors and residents. In most of the islands the people live chiefly, or entirely on the coasts; whereas, in the estimates, allowance is made for a proportionate population in the interior.

Another error, I believe, is the supposition that the decrease of the people is entirely (or almost entirely) owing to their contact with foreigners. From personal knowledge of Polynesia I feel convinced that the people were rapidly decreasing before their intercourse with civilised races commenced.

It is also a mistake to suppose that decrease is by any means universal at the present time. While in some islands the decrease of the natives has been accelerated since they have come into contact with modern civilisation and its attendant evils, in other islands the previous decrease has been greatly retarded, or even changed into an increase, by the beneficial influences of a Christian civilisation. This change has been brought about by such causes as the following:—The partial or complete cessation of wars; the discontinuance of human sacrifices (in some islands the cessation of cannibalism may be added); the cessation of infanticide; the greater respect paid to women, which leads to their release from some of the hard work which, in heathen times (in some portions of the Pacific) fell almost entirely to their share, and the consequent increase of living and healthy progeny; the increased care taken of infants and aged people, and the general progress of industry resulting from more settled habits, which leads to a more regular supply of food.

As an example, in proof of the correctness of my statements I will cite the Samoan Islands. In the "Encyclopædia Britannica" (eighth edition) we read:—"The population of Samoa

[1] I wrote this paper some months ago, intending to send it for publication in NATURE, but I afterwards determined on withholding it for the present, hoping at some future time to discuss in a more systematic and thorough manner this subject, together with some other questions bearing on the ethnology and anthropology of Polynesia. I am now, however, induced, by the reference in Prof. Rolleston's address before the British Association at Bristol, to publish it as it was first written, hoping it may prove a small contribution towards a correct understanding of this subject.

I take this opportunity to thank Dr. Rolleston for putting in its true light the relation which the work of missionaries bears to the decrease of Aboriginal populations. It is high time that the ignorance, prejudice, and narrowness manifested by many literary and scientific men gave place to a broad, common sense, and enlightened view of the matter. Missionaries are sometimes represented as if they were the actual *destroyers* of the weaker races; a view somewhat *smartly* set forth in one of Mr. Bernard Quaritch's scientific book catalogues (No. 294, Jan. 1875) in the following words:—"The missionary is a grand and striking figure in the history of the world. Robed in black, and bearing the *Word of Life*, he moves among the weaker races of mankind; around his path they sicken and perish, and countless nations of men are swept away." In Polynesia, the agents of the London Missionary Society, at least, usually dress in *white*, and not in *black*, and I imagine most sensible missionaries who live in the tropics, do as we do in this respect. But whether we wear the ominous black, or adopt the more hopeful (or comfortable) white, I fancy Mr. Quaritch is guilty of what the logicians call an *ignoratio elenchi*.

S. J. W.

Samoa, Dec. 30, 1875

has been variously estimated from as many as 160,000 to as few as 38,000. The Rev. J. Williams estimated them at the former number in 1830, and Capt. Erskine, in 1854, at the latter; but by the missionaries (*Samoan Reporter*, 1845), the population was reckoned at from 50,000 to 60,000. At present the Samoan nation does not probably exceed 40,000 souls" (vol. xviii. p. 278. See also vol. xvi. p. 88).

In 1853 the first census of the population of these islands was taken, and it was then found that the natives numbered 33,901. Thus, according to the Rev. J. Williams's estimate, there was a decrease of 126,099 in twenty-three years, or 5,482 per annum! According to the lowest estimate of the missionaries in 1845, there was a decrease of 16,099 in eight years, or 2,012 per annum! Capt. Erskine's more moderate estimate was 4,099 above the actual number ascertained by census the year before he made it.

In 1863 a second census of the population was taken, and the natives then numbered 35,097, showing an increase of 1,196 in ten years, or $119\frac{6}{10}$ per annum.

In 1874 another general census of Samoa was taken, and the entire native population was found to be 34,265, showing a decrease of 832 in the eleven years since 1863, but still giving an increase, in the twenty-one years since 1853, of 364: the decrease during the shorter period averaging $75\frac{7}{11}$ per annum, while the increase during the longer period averages $17\frac{1}{3}$ per annum. This difference is easily accounted for. During the eleven years which intervened between the second census and that recently taken, there was a civil war in the principal islands which lasted more than four years, in consequence of which the usual death-rate was largely increased. This was not merely owing to the actual number of people killed in fighting, but chiefly to privation and suffering in those districts where the fighting took place. The census shows a decrease on the different islands in proportion to the amount of damage done, and the consequent privations suffered by the people. Thus Upolu, which was the principal seat of the war, suffered very severely; and here there was a decrease of 988 in a population of 17,556, or more than 5 per cent. Savaii, which suffered comparatively little, shows a decrease of 140 in a population of 12 670—slightly over 1 per cent. On the other hand, the island of Tutuila, which was not involved in the war, shows an *increase* of 296, or more than 8 per cent. in the eleven years: the population in 1863 being 3,450, while in 1874 it amounted to 3,746.

In one part of Upolu, where a register of births and deaths was kept for several years previous to the above-mentioned war, there was an annual excess in the number of births over the deaths, averaging from 1 to 2 per cent. I believe the decrease in the aggregate population during the eleven years is entirely owing to the war.

The population of the small island of Niuē (Savage Island) was counted in 1859 and found to number 4,300. It was counted again in 1864, and found to number 5,010, showing an increase of 710 in five years, or more than 3 per cent. per annum. In 1868 the population was again numbered, and found to amount to 5,060, showing an increase of fifty only in four years. But at the latter date many of the natives were away as voluntary immigrant labourers in other islands—seventy-five being in Samoa—and many others were sailors on board vessels: hence that does not represent the actual increase. I know many other islands in Polynesia where there is a steady increase in the population year by year, since the abolition of paganism.

But notwithstanding these facts, which give some hope for the Polynesians, I fear the balance is against them in the aggregate, and that the general tendency is towards a more or less rapid decrease which—unless some measures for their conservation are found—will greatly diminish, if not destroy them. The causes which produce this tendency are, *first*, those epidemic diseases which commit such fearful havoc in localities to which they are newly introduced. Some of them, such as influenza and measles, are comparatively harmless in countries where they have long been prevalent. But they are terribly fatal in a new country, as has lately been seen in Fiji. This excessive mortality is not, I believe, owing to the want of stamina in the constitutions of the natives; but may be accounted for by their mode of life, and by the fact that the inhabitants of entire villages are stricken together, leaving none in health to procure food for, and attend to, the sick.

But fearful as the effects of these epidemic diseases are, they do not recur, and, in my opinion, there are other causes which, in the end, prove themselves far more destructive. These are constantly working, and are every day working with augmented power; and these the Polynesians owe entirely to their intercourse with foreigners. They are *ardent spirits* and *syphilis*. In the case of the Hawaiian Islands, *leprosy* may be added; for in that archipelago these three scourges are working with fearful effect, and they bid fair to sweep off the greater part of the natives. But those islands must not be taken as fairly representative of the state of Polynesia as a whole. In many islands the drinking of foreign spirits is almost unknown, and in many more syphilis is rarely if ever met with.

The question may be asked, What possible remedies can be suggested which may, by moderating, or removing, the causes of decrease, help in the conservation of the Polynesians? The only possible remedies which at present occur to me are: (1) Strict quarantine regulations wherever there is a government by which they can be enforced. (2) A heavy duty (which would be, practically, prohibitory) on the deleterious kinds of spirits commonly imported into the islands and vended to the natives.

The introduction of measles into Fiji since the establishment of British rule there does not speak very strongly in favour of the efficacy of the first remedy. But there surely must have been some serious oversight or neglect on the part of medical officers, when infected persons were permitted to land on those islands from a British man-of-war, and such oversight or neglect ought not to be repeated elsewhere.

It would be a blessing if some measures could be taken to protect the Polynesians against one of their worst enemies—ardent spirits. It is notorious that an immense quantity of a noxious kind of spirit is constantly imported into some of the islands and sold to the natives. The taste for this deleterious drink is increasing, and likely still to increase. If low traders will continue to vend such a vile compound, without regard to the amount of human misery, or even loss of life, which may result therefrom, it appears to me that all respectable merchants who do business in Polynesia should set themselves against it and keep their hands clean from the traffic.

Wind Driftage

IN the interesting narrative of the cruise of the *Challenger* that appeared in NATURE (vol. xiv. p. 93), the wind-formed rocks and drift of the Bermudas are referred to. This probably will call attention to the much-neglected subject of wind driftage; but I sincerely trust Prof. Thomson and his Colleague will discard such an ill-advised name as "sand-glaciers" for the inundations of "Æolian" or "blowing sands." The term glacier belongs to ice; beside, these sand-streams do not act like glaciers, their advance being more similar to that of a lava flow.

Somewhat similar sands occur in Australia, and were described years ago under the name of "Æolian drift," by an officer of the Royal Engineers (whose name I now forget), those in the vicinity of Melbourne Bay being remarkable for containing regular strata of empty bottles. In Kutch there are extensive wind-formed rocks, in some, such as Meeta and Kara, the cement being principally salt. On the coast of Ireland travelling sands can be studied on a small scale. At Bundoran, the late Lord Palmerston stopped the Æolian drift from travelling by planting it with the Austrian pine; on the west coast in places considerable encroachments take place, one of the most conspicuous now in progress occurring to the east of Broad Haven, co. Mayo. Here, a few years ago, the "bent," or grass on a large accumulation of sand was cut by the natives, and the sand began to travel eastward. Now it has destroyed several hundred acres of tillage land and driven the inhabitants before it over the brow of the hill into a boggy valley. G. HENRY KINAHAN

Freezing Phenomenon

PROBABLY the following statement may be of use, probably also it is nothing new, but in the faint hope of its being a mite of value, I send it.

In a wash-hand basin, placed in an out-house where fine dust fell on the surface of the water, I noticed this last winter, that there was a thin sheet of ice atop, and that the dust had fallen to the bottom of the basin, and there was arranged in precisely the same patterns as were to be seen in the hoar-frost on the panes of glass of some neighbouring hot-beds.

This would seem to show that, in freezing, water goes through a series of fantastic movements.

Could such motions be at all comparable with the changes that the particles of iron go through from cold, and occasionally

rendering a supposed good piece of metal quite brittle and dangerous if trusted to do its ordinary duty, such accidents happening as a rule in cold weather?

Sagacity in Cats

THE following facts are curious: I should be glad if any of your readers can inform me whether anything of the kind has been already noticed. I have a cat of half-Persian breed; she is about eight years old, and has always been remarkable for her aversion to strangers, more especially to children. If children have at any time come into the house where she was, she has invariably decamped and secreted herself. She never could bear to be handled or pulled about (which so many cats seem to enjoy) by anyone but by her master.

During the present year this cat has remained in Scotland; a few weeks ago my little boy went to reside in the house where the cat is at present. This boy is just at that age when children delight in pulling about everything they can get hold of: naturally a cat was a perfect godsend to him. After a few days the cat was seen to smell the child repeatedly; she seemed to be satisfied of his relationship, and since that time she follows him about the house (a thing which she never did to anyone but her master), rubs herself against him, and allows him to pull her tail and ears and draw her about by the legs.

Owens College, June 22 M. M. PATTISON MUIR

OUR ASTRONOMICAL COLUMN

LE VERRIER'S TABLES OF SATURN.—Vol. xii. of the *Annales* of the Observatory of Paris, containing, in addition to his Tables of Jupiter, the more extensive Tables of Saturn, was presented by M. Le Verrier to the Academy of Sciences on the 5th of the present month. To insure, as M. Le Verrier has explained, their accurate and convenient application, the Tables of Saturn occupy two-thirds more space than those of Jupiter, or 278 and 170 pages respectively, though their general form and arrangement appears to be the same, and as those who have seen the Tables of Jupiter will be aware, is materially different from the arrangement of the Tables of Mercury to Mars inclusive. The tables of Saturn represent exactly the observations from Bradley to the present day.

M. Le Verrier again mentioned that his theories of Uranus and Neptune were complete, and susceptible of being extended to an indefinite number of years. The comparison of the theories with observation is already sufficiently advanced to enable him to pronounce upon their satisfactory agreement.

36 OPHIUCHI.—It appears to have been somewhat hastily concluded that this star, so remarkable for its identity of proper motion, both as regards amount and direction with the distant 30 Scorpii, is also a binary system. So far the measures by no means bear out this inference, and unless they are affected with unusual errors it is not easy to explain them. For comparison the following may be selected:—

Herschel and South	1822·52	Pos.	227·4	Dis.	5·55
Herschel	1835·19	,,	223·5		4·88
Dawes	1841·59	,,	219·3		4·78
Jacob	1846·21	,,	216·2		4·66
,, ...	1850·62	,,	214·9		4·49
,, ...	1854·07	,,	214·4		4·13
Barclay	1871·51	,,	210 6		5·01

It might be supposed from these measures, that while the angle has been slowly retrograding between the years 1822 and 1871, the distance had diminished until 1854, and is now on the increase, but on projecting the measures it will be seen that this would indicate a motion of one star in a curve convex towards the other. If there are material errors of observation, the real motion of the companion may be rectilinear, or the change in angle and distance may be caused by a slight difference in the proper motions of the stars. Further careful measures, however, are yet required before any safe inference can be made, and more especially in latitudes where the star r... to a greater altitude than in this country. Capt. Jacob's comparatively small distance in 1854 is not supported by the meridian observations at Greenwich, Oxford, and Washington, from which we might conclude, it was nearly one second greater than his result, but meridian observations are not always reliable for such delicate comparisons, and besides it seems hardly probable that so practised and excellent an astrometer as Capt. Jacob would be in error 1″ in the distance of so easy a star, favoured as he was by his positions at Poona and Madras; Secchi also is confirmatory. The statement of Chr. Mayer that the companion was 13″·2 due S. of the principal star, or on an angle of 180° (not 360° as given by Smyth in the "Cycle"), does not assist an explanation.

NOVA OPHIUCHI, 1848.—This star has been a difficult object for the generality of telescopes during the last few years. In 1856 it had descended to the eleventh magnitude; ten years later it was a faint twelfth, and in 1874-75 not higher than thirteen in the scale in ordinary... Herr Julius Schmidt carefully examined the vicinity at Athens in August 1867, fixing the positions of the small stars near the variable, which were discernible in the 6-feet refractor of that observatory. These places are here brought up to the beginning of the present year, with the view to facilitate the recognition of the object which became so suddenly conspicuous to the naked eye at the end of April 1848. The magnitudes are Schmidt's.

No of Star.	Magnitude.	R A. h. m. s.	N P.D. ° ′ ″	
1	11	16 52 3·9	102 46 1	
2	13	16 52 28·7	102 44 4	
Nova	Var.	16 52 33·1	102 42 3	From the first Radcliffe Catalogue.
3	11	16 52 55·4	102 49 12	
4	11	16 53 2 5	102 34 1	
5	10·11	16 54 19·8	102 49 6	

The ninth magnitude, Lalande 30853, R.A. 1876·0, 16h. 52m. 18 5s. N.P.D. 103° 0′ 24″, may be used to identify the variable which it precedes 14 6 seconds, and is 18′ 21″ more southerly. Schmidt thought there might be a star 13·14, following the variable 5s. or 6s. His stars (1) and (3) had these position-angles and distances, while *Nova* was still visible without the telescope in 1848.

(1) Position ...	249·4	Distance ...	475″·4
(3) ,, ..	144·5	,, ...	530·8

The star (2) was repeatedly measured in position and distance in 1848, with the 15-inch refractor at Harvard College by the Bonds, with the view to discover if there were appreciable parallax in the variable; it is called a fifteenth magnitude in the Harvard scale, and by a mean of ten nights' measures its position was 212°·11, and distance 115″·65 for 1848·52.

STEPHAN'S COMET, 1867 (I).—This comet, for which Mr. Searle found an elliptic orbit, period 33·62 years, or almost precisely that of the comet of the November meteors, and which was shown some years since to make a very near approach to the orbit of the planet Uranus, appears also to pass at a short distance from that of Mars. In heliocentric ecliptical longitude 81° 53′, and latitude + 1° 5′, with true anomaly, 6° 10′, the distance between the two orbits is only 0·0207, thus affording a similar instance of close approximation to this planet which Dr. Brünnow found to take place in the case of De Vico's comet of short-period. It is singular that a comet's orbit should lie so very near to the orbits of two of the planets, in one instance near its perihelion, and in the other not far from aphelion.

THE COMET OF 1698.—In the first orbit of this comet in the last *Astronomical Column*, the perihelion passage should be dated *October*.

THE SATELLITE OF VENUS[1]

AN indirect result of the recent Transit of Venus has been the revival of a nearly forgotten but not uninteresting speculation as to the possible existence of a satellite accompanying her. Nothing of the kind was observed on the late occasion, but the planet's path was so far from central that an attendant might readily have remained outside the solar disc; and therefore, though the negative evidence, if it had required additional strength, would have received it from this non-appearance, it would not have been rendered absolutely conclusive on that ground alone; and, so far as the Transit is concerned, there is still room for an essay like that before us, which, previous in composition though subsequently published, advocates the affirmative opinion. That opinion, after so many years of additional observation since Lambert's memoir in 1777, is not likely to find favour with astronomers now, and certainly will not be established by the present treatise. It is an unpleasant task to express any other than a favourable estimate of any work undertaken with a view to enlarge the boundary of knowledge; but in the present instance it is unavoidable. There is, indeed, a very considerable accumulation of historical matter, and there are some pleasant anecdotes, and a few valuable and little known facts; but the materials of some portions at least are neither complete nor accurate; the pretermission of recent discoveries especially spectroscopic is sometimes simply unaccountable; and the hypotheses occasionally partake of an extravagance that outstrips all probability. The subject is, however, as has been remarked, not devoid of some interest, nor, to say the truth, disentangled from some perplexity of an obstinate character; and it is worthy of a more satisfactory elucidation, which might be comprised in a narrow compass, as its literature is not extensive. A few remarks only can be attempted here.

That something strongly resembling a satellite has been occasionally seen near Venus, especially about the middle of the last century, is beyond a doubt. It is equally certain, and familiar to all experienced observers, that reflected images, or technically "ghosts," may, under certain circumstances, be formed in the eye-piece of the telescope, and might be the means of causing deception: and the whole matter is reduced to the simple inquiry, whether all the recorded instances admit of this easy explanation; though, if they do not, it must be remembered that the existence of a satellite would not necessarily follow.

The Abbot Hell, who published an elaborate dissertation on the subject in the appendix to the Vienna Astronomical Ephemerides for 1766, seems to have been the first to study systematically the formation of telescopic ghosts. The Vienna Observatory was possessed in those days of two good English telescopes, left to it in 1757 by Cardinal de Trautson; a 2 ft. Gregorian, and a $4\frac{1}{2}$ ft. Newtonian. About December in that year, the Abbot, examining Venus with the former instrument and a power of 70 or 80, perceived a star of an ill defined aspect near it like a little comet, but as it was invisible both in that Newtonian and in another of the same construction of 4 ft., he referred it to a reflection from the interior of the tube. In March 1758, Venus being at her greatest elongation, the illusion returned, on which he blackened the tube, and for some days did not see it again; but when at length it reappeared, on moving his eye very gently towards the eye-piece he found it change into a perfect image of a satellite with the phase of the primary. Beyond the limit of barely half a line either way from this position, it was invisible. When Venus occupied the centre of the field, this "spectrum," as he calls it, was near the edge; as he moved his eye round, or up and down, the image moved the same way, generally disappearing in the neighbourhood of the planet. A set of experiments instituted in consequence satisfied him that this image was formed by rays reflected first from the convexity of the "pupil" (cornea), and a second time from the concave face of the meniscus lens which in this case formed the eye-glass, though it would be shown by any eye-piece possessing a surface concave towards the retina. Cases were even possible, but difficult in management, when an image might be seen, though the object was not in the field; but this was formed by rays passing outside the telescope, and the ghost would be inverted and of much smaller dimensions. The magnitude of the image would depend on the proportion of curvature of the reflecting surfaces. This being once understood, the Abbot found that he could always produce, for himself or others, a spurious satellite of Venus, or Mars, or Jupiter, under the following essential conditions:—That the power should not be less than 50 or 80, or the image would be too minute to be visible, or would only resemble a small star;—that the eye must be placed at a definite distance from the eye-glass, and be moved most deliberately and cautiously backwards and forwards to find that point, the limit of visibility being sometimes only a quarter of a line either way;—and that the eye must be a little on one side of the optical axis, or the image will coincide with its primary. And it becomes readily intelligible why an observer, ignorant of these conditions, may never be able to recover an image which he had once accidentally seen. Thus far, in substance, the astronomer of Vienna, who certainly deserves credit for his ingenious and careful investigation. His reasoning is, nevertheless, a curious and instructive exemplification of the way in which a preconceived opinion may block up the mental view, and prevent a sound argument from being carried out to its legitimate consequences.

We are now in a position to examine how far this criterion is applicable to the recorded phenomena. Of these, Dr. Schorr has enumerated sixteen, in a table taken apparently from Lambert, but with the addition of an observation by Andreas Meier (Mayer). Hell had given three from Fontana, but Lambert seems to have thought one only of any consequence, and even this may well be omitted, leaving the following for our consideration.

The name of Cassini at the head of them at once commands attention, but there is nothing in his two observations in 1672 and 1686 that does not lend itself to Father Hell's hypothesis, excepting the care and experience of such an observer, who must have been familiar with every telescopic defect. The observation of Meier, which seems to have lain unnoticed in the *Astron. Jahrbuch*, 1788, till brought forward by Schorr, is on that account worthy of being cited in full. "1759, May 20, about 8h. 45m. 50s., I saw above Venus a little globe of far inferior brightness, about $1\frac{1}{2}$ diam. of Venus from herself. Future observations will show whether this little globe was an optical appearance or the satellite of Venus. The observation was made with a Gregorian telescope of thirty inches focus. It continued for half an hour, and the position of the little globe with regard to Venus remained the same, although the direction of the telescope had been changed." During so lengthened an observation it seems natural to suppose that the eye must have been repeatedly removed and replaced, which could not have occurred without the detection of an optical illusion.

In 1761, when the expected transit drew attention to Venus, Montaigne, at Limoges, was persuaded to undertake the inquiry, though he had little faith in the existence of the satellite, and was not greatly disposed to enter upon an examination in which so many great men had failed. However, on May 3 he saw a small crescent

[1] "Venusmond," &c., von Dr. F. Schorr. Braunschweig, 1875. pp.

20′ from Venus; it is expressly stated that the observation was repeated several times, and that after all he was not certain if it was not a small star; which, with a power of between forty and fifty, was not surprising. The next evening and on the 7th and 11th it was again seen, rather more distant, and each time in an altered position, but with the same phase as its primary; and on the 7th it was seen, and even much more distinctly, when Venus was not in the field. The improbability is obvious of such persistency in an illusion so readily detected. The cause may indeed have lain in the object-glass; such telescopes have been known. Wargentin, at Stockholm in the same year, found that his instrument produced a deception from this cause; and the 6-inch Cauchoix achromatic at Rome showed minute comites to bright stars a little too frequently for the credit of those who trusted it. Montaigne's changed position-angles may be thought to indicate this cause of error, as his 9-ft. refractor probably admitted of rotation in its bearings, but it is a singular coincidence that these changes should all have been in the direction of orbital revolution, and still more, in such proportions as to be reconcilable with Lambert's calculated period of about eleven days; and it is quite unintelligible that he should not have subsequently detected the fault in his telescope, as from his estimation of angles and distances he was evidently not a novice in observation. Three years later, in 1764, Rodkier, in Copenhagen, saw such an appearance on two evenings with a power of thirty-eight on a 9½ ft. refractor; on the latter occasion with a second telescope also. There is little in this to contravene the Vienna theory, especially as this second telescope had a coloured meniscus eye-glass, and he failed in finding it with two other instruments: but it is more remarkable that on two evenings a week later the same telescope told the same tale to four different observers, one of whom was Horrebow, the Professor of Astronomy, and who, we are assured, satisfied themselves by several experiments before the second observation that it was not a deception. That the necessary conditions for its being such could have been maintained before so many eyes, is, notwithstanding its admitted pale and uncertain aspect, what could not possibly have been anticipated. But we have not yet done with this temporary outbreak, so to speak, of visibility. Before this month of March was ended, Montbarron at Auxerre, far removed from all possibility of communication, and with a very different kind of telescope, a Gregorian reflector of thirty-two inches, which of course was fixed as to its optical axis, perceived on three separate evenings, at different position-angles, something which, though it had no distinguishable phasis, was evidently not a star, and which he never could find again.

There remains still the observation of the celebrated optician Short. It is indeed chronologically misplaced here, but has been intentionally deferred as affording the strongest point in the whole affirmative evidence. As his own account is an interesting one, and has seldom, if ever, been reprinted, our readers may not be displeased to see it here as it stands in Phil. Trans. vol. xli.:—

"An Observation on the Planet Venus (with regard to her having a satellite), made by Mr. James Short, F.R.S., at sunrise, October 23, 1740.—Directing a reflecting telescope of 16·5 inches focus (with an apparatus to follow the diurnal motion) towards Venus, I perceived a small star pretty nigh her; upon which I took another telescope of the same focal distance, which magnified about fifty or sixty times, and which was fitted with a micrometer in order to measure its distance from Venus, and found its distance to be about 10° 2′ 0″ (*sic*). Finding Venus very distinct, and consequently the air very clear, I put on a magnifying power of 240 times, and to my great surprise found this star put on the same phasis with Venus. I tried another magnifying power of 140 times, and even then found the star under the same phasis. Its diameter seemed about a third, or somewhat less, of the diameter of Venus; its light was not so bright or vivid, but exceeding sharp and well defined. A line, passing through the centre of Venus and it, made an angle with the equator of about eighteen or twenty degrees. I saw it for the space of an hour several times that morning; but the light of the sun increasing, I lost it altogether about a quarter of an hour after eight. I have looked for it every clear morning since, but never had the good fortune to see it again. Cassini, in his Astronomy, mentions much such another observation. I likewise observed two darkish spots upon the body of Venus, for the air was exceeding clear and serene."

It has been justly asked by Schorr whether this observer, who was the greatest optician of his time, must not have known his telescopes better than to mistake the reflection of Venus on the eyeglass for a satellite? And Lambert puts the case very strongly, remarking that Short had the object before him for a whole hour with greatly varied powers, and it is not probable that he kept his eye immovable all the time, and after every change in the telescope replaced it at the precise point where the apparent position and distance from Venus would continue unaltered, especially as he used so high a power, with which the slightest change would have been remarked, and a micrometer, the employment of which would have necessarily implied movement in the eye. Lambert might have further strengthened his argument had he had an opportunity of consulting the original record, which shows that another telescope was employed, making in all four eye-pieces, and that Short viewed it not continuously, but at intervals during an hour, increasing every time the chance of detection; nor should the important consideration be overlooked that, with the higher powers, the apparent motion of the planet through the field would be rapid enough to give the illusion a movement in the reverse direction, which would unmask it at once. An examination of one of Short's reflectors might be necessary to decide whether with *his* power of 240 (he was said to have considerably over-rated his magnifiers) the field would have included the attendant with the primary.

The evidence against Father Hell's explanation had even previously become very formidable. The conditions under which his "ghost" is visible are so restrained, the limits so narrow, that there is considerable presumption in any individual case against such an illusion having been formed, or at least against its having passed unchallenged, when a trifling change in the supposed obliquity of indirect vision would at once shift the position of the false image with respect to its origin, and an equally minute alteration in the distance of the eye would deface or obliterate it. But if this is so in each separate instance, the enumeration of so many, with instruments and observers so varied, increases the improbability afresh at every remove, and the careful observation of a man like Short is peculiarly conclusive against the possibility of deception, at least from the assigned cause.

Thus far the advocates of a satellite have it their own way; and to what has been said they would add some curious facts as corroborative evidence. The object, when its size has been remarked, has always been recorded of the same magnitude, one-fourth, or less than one-third, of its primary. It showed itself seven times in one month (March 1764), at a period when telescopes were no longer in their infancy, and in two places at a great distance from each other. And its position-angles, which chance would have placed anywhere, agree sufficiently well with orbital revolution to admit of the calculation of a period, which Lambert has given at 11d. 5h., to which, however, Schorr prefers his own of 12·17d. Many astronomical details are probably accepted among us for which there are no stronger grounds of belief.

But it is one thing to invalidate an opponent's conclu-

sion—another, to establish one's own. As we have already remarked, the abandonment of Hell's solution is not the demonstration of a satellite; and we have yet to hear the opposite side. Some adverse points we have noted as we have passed along; and we might have added the fact that at the epoch of Rodkier's second observation Uranus and Venus were not far apart; perhaps "within blundering distance." But of course the main strength of the denial lies in the fact that, though the alleged appearance can require but little optical advantages, it has been so frequently sought in vain through a long series of years. During that very spring of 1764, when the primary occupied an especially favourable position, it was very carefully looked for by many observers—among others, the acute and experienced Messier, but nowhere seen except at Copenhagen and Auxerre. Cassini and Short, with interest awakened by their own apparent success, could never with all their diligence recover it; and the latter, twenty-three years after his own striking observation, was thought by Lalande, then in London, to disbelieve the satellite's existence. Not to mention Bianchini and others, the elder Herschel never saw a trace of it; nor Schroter, the close observer of Venus during fifteen years; nor Harding, nor Struve, nor Lamont, Smyth, De Vico, Secchi, or any other of the first observers armed with the first telescopes of modern times. And though the subject has now ceased to attract attention, yet, in the unprecedented multiplication of observers and instruments, it would hardly have had a chance of escape. On the whole, therefore, though the evidence may exclude the intrusion of an ordinary "ghost," it seems irresistible against the reality of a satellite.

What, then, was that which was seen? for that something really has been seen, the character of some at least of the witnesses renders a certainty. A reflection in the telescope independent of the position of the eye would have been always visible as a permanent defect; and the fact of its never recurring is equally adverse to the idea of a satellite, and that of an instrumental deception. The only alternative which remains would seem to be that of atmospheric reflection, or "mirage." There would certainly be some difficulty in finding a parallel among recorded facts, though Brewster, if I recollect aright, speaks of having once seen two images of the crescent moon; but the known instances of atmospheric illusion are some of them so very strange and inexplicable, and yet so abundantly attested, that we may possibly, though with little confidence, seek in this direction a solution of the ancient mystery.

Before concluding these remarks, I may be permitted to relate something which fell under my own notice many years ago, and which may perhaps have some connection with the present subject. The observation which I am about to describe took place in the year 1823; it was not reduced to writing till nine years afterwards, but the recollection of it was then very vivid and fully to be trusted; and a small diagram of the relative position of the objects made at the time in the margin of a pocket-book of that year fixes the date to May 22. Until that evening I had never seen the planet Mercury, but finding that he was then in a favourable position I looked out for him with a little common hand-telescope (my near sightedness and the want of an eye-glass preventing me from detecting him otherwise), and soon found him low in the sunset horizon. The telescope in question had a good achromatic object-glass of 1·3 inch aperture and 14 inches focus, and was fitted with a terrestrial eye-piece, magnifying perhaps thirteen or fourteen times; it was a favourite instrument in those early days, and I had succeeded in detecting with it several of the brighter nebulæ and clusters, especially, at the extreme limit of visibility, the large nebula in Triangulum (M. 33). When I had looked at Mercury, I turned to Venus, then high in the S.W., and saw a star, exactly resembling Mercury, or a miniature Venus, *p* or *s p* the planet, at a short distance, perhaps 20′ or 30′, and ¼ or ⅓ of its diameter, or rather its impression on the eye, as of course with so low a power the disc of the planet could not be well made out. I had, when I wrote, a very distinct recollection of its great resemblance to Mercury. My mother, who had an excellent sight, coming into the garden, I showed her Mercury and this appearance with the glass, and she not only saw it readily, but we both believed afterwards that she perceived it without that aid. On the next evening, or more probably on the next but one, I could not find it again. As far as I can ascertain, I had in those early days no knowledge of the suspicion that had been entertained of a satellite: and I did not enter it, as in that case I should have done, in a little note-book of remarkable phenomena that I kept. Through the kindness of Mr. Lynn I have been enabled to ascertain that the star ε Geminorum was not far from the planet on that day, only about 30½′ further S., which would agree very fairly in that direction, but lying 6½ m. more to the E. Independently of this discrepancy—a serious one, for I have no doubt of the *p* or *s p* position of the satellite, not only clearly remembered but shown in the little diagram—it does not seem probable that a star of 3–4 mag. should have been so conspicuous in such an instrument in the twilight. I have no note of the hour, but as Mercury had not sunk into the smoke of the town (Gloucester) in the W. horizon, it must have been comparatively early, and at that time of year the twilight is strong. It may be too hazardous under all the circumstances to include this with the other observations of the pseudo-satellite, but there seems no reason why it should pass into entire oblivion.

T. W. WEBB

THE MISSING LINK BETWEEN THE VERTEBRATES AND INVERTEBRATES[1]

THE views which Dr. Dohrn has recently put forth as to the details of the steps by which the vertebrate stock arose out of an ancestry not very much unlike the existing Annelids, are of such interest that, notwithstanding previous reference to the subject, no apology is needed for presenting the readers of NATURE with a condensation of the main argument contained in "The Origin of Vertebrata."

Dr. Dohrn first draws attention to the correspondences between vertebrate and insect embryos, which have been too little regarded in consequence of our designating the nervous side in the one as dorsal, in the other as ventral. Yet the facts that, in both, the nervous system is developed on the convex side of the embryo and acquires a strong convex flexure anteriorly, and that the body-cavity is finally closed up on the side of the body opposite to the nervous system, point to a common origin at a comparatively high level. The surface of the animal which is called ventral is determined by the presence of the mouth on that surface; and if any Vertebrates had a mouth-opening between the brain and the spinal cord on the dorsal surface, that dorsal surface would necessarily become ventral. Since, moreover, the ancestors of the Vertebrata must have had a nervous ring surrounding their gullet, it would appear more reasonable to suppose that the mouth-opening had been changed in the course of development than that the situation of the nervous centres had been altered. We are thus led to look for traces of an old mouth-opening on that surface of the early Vertebrates which corresponded to our dorsal surface, and to seek reasons for regarding our present mouth as a comparatively modern development.

Dr. Dohrn believes that the old mouth passed through the nervous centres between the crura cerebelli, or more

[1] Der Ursprung der Wirbelthiere und das Princip des Functionswechsels: Genealogische Skizzen von Anton Dohrn. (Leipzig. Engelmann)

accurately, in the fossa rhomboidea, or fourth ventricle, which is remarkable for being of greater proportionate size early in development, and afterwards undergoing retrogression. At an early stage we only need to conceive a slit to be made in the nerve tube at the bottom of the fossa rhomboidea, in order to furnish a suitable passage into the alimentary canal. His first reason for regarding the vertebrate mouth as a modern structure is that it arises so extraordinarily late in development. The embryonic body is almost completely framed, all the great systems are established, the circulation is in active operation, while as yet there is no mouth. Again, the mouth does not arise in the position in which it permanently remains in the great majority. It undergoes considerable shifting forwards. Only in the Selachians and Ganoids does it retain its primitive situation. Moreover, the study of development is steadily tending to establish the idea that the mouth of Vertebrates is homodynamous with the gill-clefts. It is limited, like them, by a pair of arches, lies just in front of the first pair of gill-clefts, arises simultaneously with them in the embryo, and opens into the alimentary canal. A glance at the ventral surface of a Ray shows the likeness of the mouth to a pair of coalesced gill-clefts. Consequently, it becomes probable that the present mouth-opening once existed and functioned as a gill-cleft; that at a certain period in the ascending development, both the old and the new mouths supplied nourishment, that the latter gained the predominance, and that finally the old mouth became aborted.

The next problem attacked is the origin of the gill-clefts. A very elaborate account is given of the supposed process by which the external gills and segmental organs of Annelids were metamorphosed into the gills and gill-clefts of Vertebrates and the skeletal elements connected with them. The great difficulty which Dr. Dohrn confesses in this matter is the connection of the inner extremities of the segmental organs with the wall of the alimentary canal. But if this be granted it is comparatively easy to understand how the shortening and widening of the segmental organs might give rise to gill-cavities such as those of the Selachians. The process by which Dr. Dohrn conceives that the limbs of Vertebrata might have been developed from two pairs of gills in Annelids is a great evidence of ingenuity, though it is to be expected that it will be viewed rather incredulously.

It follows from the view of the origin of Vertebrates thus expounded that Amphioxus loses much of its interest, for there is no place for Amphioxus among Annelids, nor among the primordial Vertebrates; it lacks almost all that they possess. Yet nothing can be gained by excluding Amphioxus from the Vertebrates; for it is so connected with the Cyclostome fishes that it cannot be placed at any great distance from them; while on the other hand it is so related to Ascidians, that the latter must be included among the Vertebrata.

Dr. Dohrn then proceeds with a long argument to show that the Cyclostome fishes are degenerate from a higher type of fishes, and that Amphioxus is a result of still further degeneration. He shows how their mode of life necessitates many of the modifications they have undergone; and that the diversities of the details of structure in Cyclostomes are inconsistent with their being viewed as representing stages in upward development. Finally, the larva of Ascidians is represented as a degenerate fish—a degenerate Cyclostome possibly—which carries to the extreme all the departures of the latter from the fish-type. The most important element in this degeneration results from the fact that Ascidians, instead of being attached to fishes or to any objects from which they can derive nutriment, are fixed to stones, plants, &c., or to such parts of animals (cephalothorax of crabs, tubes of tubicolous annelids) as do not afford them nourishment. Consequently they have lost the old mouth in the organ of attachment, homologous with that of all Vertebrates, and have developed a new one, homologous with the nasal passage of *Myxine*. Thus we can explain the astonishing fact that the mouth-opening of the Ascidian-larva has a communication with the fore-wall of the so-called cerebral vesicle. It is the last vestige of the openings in the nasal sacs by which the olfactory nerves entered.

The most patent objection to Dr. Dohrn's view about Amphioxus is that it fails to account for the development of a many-segmented respiratory apparatus as a degeneration from a higher animal with a small number of gill-arches. It would appear far more reasonable to suppose Amphioxus to be a degeneration from a much lower elevation than the Cyclostome type, viz., from some stage where the respiratory apparatus retained the multiserial character derived from its Annelid forefathers.

The keynote of the author's reasonings is to be found in the principle of Transformation of Function (*Functionswechsel*), on which he lays great stress. He states it as follows:—The transformation of an organ happens through a succession of functions being discharged by one and the same organ. Each function is a resultant of several components, of which one constitutes the chief or primary function, while the others are lower or secondary functions. Diminution of the importance of the chief function with increase of the importance of a secondary function, alters the entire resultant function; the secondary gradually rises to be the chief function, the resultant function becomes different, and the consequence of the whole process is the transformation of the organ. This principle is considered to be a complete answer to the difficulty so strongly insisted on by Mr. Mivart, the incompetency of natural selection to account for the incipient stages of subsequently useful structures. Dr. Dohrn's statement of his principle does not strike us as very different from Mr. Darwin's ("Origin of Species," 5th edition, p. 251), though a little more definitely stated. Mr. Darwin says: "The same organ having performed simultaneously very different functions, and then having been in part or in whole specialised for one function; and two distinct organs having performed at the same time the same function, the one having been perfected whilst aided by the other, must often have largely facilitated transitions." The illustrations given by Dr. Dohrn of the steps by which the anterior extremities of Crustacea became applied to mastication, how the mouth of Vertebrates originated from a pair of gill-clefts, how the respiratory apparatus of Tunicates originated from that of Vertebrates, &c., are, however, exceedingly interesting.

An English translation of Dr. Dohrn's pamphlet could not fail to be serviceable to the large number of students who take an interest in the genealogical problems of morphology. G. T. BETTANY

MAGNETIC OBSERVATIONS IN CHINA[1]

THE first annual report of the magnetic observations at this new observatory has just reached Europe, and it contains results of considerable interest to those engaged in the study of terrestrial magnetism.

The position of Zi-ka-wei is 31° 12′ 30″ N., and 8h. 5m. 45s. E. of Greenwich, being rather less than four miles to the S.W. of Shang-Hai. The observatory is in possession of an excellent set of instruments for determining the absolute values of the magnetic elements, procured by the kind assistance of the Director of Kew Observatory, and a set of self-recording magnetographs by Adie, verified at Kew, have just been erected in a suitable building. The observer, the Rev. M. Dechevrens, S.J., spent a considerable time at Stonyhurst Observatory previous to his departure for China, in order to make himself thoroughly acquainted with the methods of observation, and with the use of the instruments.

The observations in the report extend from April 1874 to March 1875, and furnish the following data for the epoch Oct. 1, 1874:—

1 "Observatoire Météorologique et Magnétique de Zi-ka-wei." Chine, Magnétisme Terrestre, 1874-5.

Declination	1° 54′·72 W.
Dip	46° 15′
Total Force...	10·04850

The value of the declination is very reliable, as it depends on observations taken every half hour from 6 A.M. to 6 P.M. on four days each month in 1874, and on eight days a month in 1875. The dip results from six complete observations, and the horizontal component of the intensity was determined twice a month in 1874, and every week in 1875.

Previous dip observations at Shang-Hai, by Sir E. Home in 1843, and by Capt. Shadwell in 1858, give – 2′·2 and – 3′·4 as the secular variation for 1851 and 1862, the latter differing but slightly from the present variation in England.

Comparing the monthly means of the horizontal force for the winter and summer of 1874–75, we find an excess of 0·00074 in favour of the winter, when the sun is nearest the earth. The extreme variation is only 0·00577, and both maximum and minimum occur in the summer months.

From a limited number of night observations it appears that the range of the declination needle is much more confined, whilst the sun is below the horizon than during the day hours. The diurnal variation is regular throughout the year, but the daily changes in winter are less simple than those of summer. The following are the mean results for the separate seasons:—

	Mean. ° ′ ″	Min at	° ′ ″	Max at	° ′ ″
Spring ..	1 50 49	9 A.M.	1 47 33	2 P.M.	1 54 3
Summer	1 49 39	8 ,,	1 45 45	2 ,,	1 53 3
Autumn	1 59 35	9 ,,	1 58 9	1 ,,	2 1 10
Winter	1 58 51	9 ,,	1 57 32	1 ,,	2 0 5

The time of the principal minimum is more constant than that of the maximum, the latter being anticipated by one hour in winter.

A sudden change from 1° 50′ 13″ on Sept. 21 to 1° 56′ 51″ on Sept. 26, 1874, seems to require further confirmation (which it did not receive in 1875) before it can be considered as more than accidentally connected with the passage of the sun through the autumnal equinox.

The monthly mean value of the declination is greatest in November and least in June, and the absolute maximum and minimum were:—

2° 3′ 49″ at 11h. 15m. A.M. on November 8,

and

1° 41′ 58″ at 9 A.M. on June 29.

giving a yearly range of only 21′ 51″, whilst the secular variation amounts to + 5′·85 The value on Nov. 8 was also evidently increased by some irregular disturbance.

The comparison of the yearly means for the different hours with the hourly means for each season, shows that the sun's position with regard to the equator has a decided effect on the magnetic declination, as increase and diminution in summer invariably correspond with diminution and increase in winter.

In discussing the hourly velocity of the needle, it is found that the acceleration is greatest between 10 and 11 A.M., when the magnet is near its mean position, and that the A.M. maximum velocity is an hour earlier, and the P.M. maximum an hour later in summer than in winter, the greatest velocity being about 1″·5 per minute.

The mean amplitude of the daily excursions of the declination magnet is 7′·88 in summer against 3′·68 in winter, June giving the maximum mean amplitude of 9′·06, and December the minimum of 2′ 95. The value of 1′·92 in February appears to be exceptional. The greatest extent of a daily oscillation in the course of the twelve months was 11′·05 on June 1, and the least 1′·13 on Feb. 20, giving a maximum yearly variation of 9′·92.

The changes of the magnetic elements appear to be remarkably small throughout, and very free from irregular disturbances. The care with which the observations are taken, and the efficient way in which they are discussed, are an earnest of the plentiful harvest we have every reason to expect from this land once so famous, but hitherto so neglected by modern science.

Stonyhurst Observatory, April 13 S. J. PERRY

THE CHALLENGER EXPEDITION

WE have great pleasure in availing ourselves of the permission to publish the following correspondence which has passed through our hands, and in congratulating the staff of the *Challenger*, on having deserved so weighty a testimonial of success. It is an additional assurance that their three years' labour has not been in vain, that so many distinguished men of science have been impelled to speak of it in such terms, as well as a guarantee to the British Government that they did a wise thing in equipping the expedition; we hope it will be an encouragement to the latter to continue to deserve such golden opinions.

To the Editor of "Nature"

Vienna, June 12, 1876

SIR,—After having followed the reports of the naturalists of H.M.S. *Challenger* with the utmost interest, we beg leave to ask you kindly to transmit this simple but sincere expression of a hearty welcome and of thankful admiration to these distinguished gentlemen, as well as to the officers and the crew of this gallant ship, which has been called to render such prominent services to science. Yours most respectfully,

EDW. SUESS, M. P. Prof. University, Vienna,
C. CLAUS,
G. TSCHERMAK,
F. STEINDACHNER, Director of the Imper. Zoolog. Museum,
DR. FR. BRAUER, Custos of the Imper. Zoolog. Museum,
E. V. MARENZELLER,
Prof. Dr. J. HANN,
F. KARRER,
TH. FUCHS, Custos am k.k. Hof. Min. Cab.,
PELZELN, Custos am k.k. Zoolog. Cabinete.

To this the following reply has been made by Sir C. Thomson:—

To the Editor of "Nature"

20, Palmerston Place, Edinburgh, June 23, 1876

MY dear Sir,—I received your note and enclosure last evening. Will you allow me through you to express on my own part and on that of my colleagues Civilian and Naval on board the *Challenger*, our deep gratification at the kind way in which the leaders of Natural Science in Vienna have expressed their approval of our efforts to extend the limits of knowledge in Physical Geography?

We hope that the Empire, which by the most instructive voyage of the *Novara* immediately preceded us in a similar line of research, may be among the first to aid in filling up the rich details of the new zoological region of which we have been able hitherto to supply only an outline.

I am, my dear Sir, yours very faithfully,

C. WYVILLE THOMSON,
Director of the Civilian Scientific Staff of the *Challenger* Expedition.

ABSTRACT REPORT TO "NATURE" ON EXPERIMENTATION ON ANIMALS FOR THE ADVANCE OF PRACTICAL MEDICINE[1]

III.

Experimental Researches on Anæsthesia Local and General.

THE revival of methods for rendering surgical operations on men and animals perfectly painless, while it has been one of the greatest of the advances of modern medical art, has not been without its alloy. The present generation can scarcely appreciate what were the scenes of the operating theatre before the introduction of anæsthesia. The present generation that is not medical cannot appreciate now what is the scene at an operation when the agent employed to prevent pain proves an agent of death. One surgeon I know has been present at six of these fatal catastrophes under and from anæsthetics. Such an experience shakes the strongest heart. Here is a human being talking cheerfully and resigning himself with full confidence to his medical friends. The operation to be performed may be the act of seconds

[1] Continued from p. 152.

only, but the dread of the pain enforces on the operator the necessity of administering the anæsthetic. A few inhalations of the narcotic vapour are made, and in an instant the body, a moment or two ago animated and full of life and energy, is lifeless in the hands of the administrator of the narcotic.

There is no more painful agony to a practitioner of medicine than a catastrophe of this character. He feels as if the whole beneficent art of anæsthesia were, after all, a mockery; as if it were better that tens of thousands should suffer pain than that one should die under his directing hand merely to save a brief period of pain.

From the first of the reintroduction of anæsthetics these unhappy fatal failures from them have occurred to darken with the shadow of death the retreat of pain from the earth. What more natural, what more humane a labour than that which is devoted to the discovery of a means by which this shadow of death may also be made to fade from the picture? To me this labour has been a life's work. I have pursued it in two directions.

(a) By endeavouring to discover anæsthetic methods which shall carry with them no danger to life

(b) By endeavouring to discover means that shall restore safety when danger is incurred from the use of the present imperfect anæsthetics.

In conducting both these lines of research it has been necessary to experiment on the inferior animals. There is no other method. If the most promising new chemical agent for anæsthesia were put into my hands to-day by the scientific chemist, I could not administer the agent direct to the human subject on mere speculation. It is true I have, from long experience, been able so to understand the characters of anæsthetics that I can formulate them theoretically. If the chemist gives to me a substance and tells me its atomic composition, its physical properties of solubility, of weight, vapour density, and boiling point, I know at once whether it is or is not an anæsthetic, and I can reject on the spot some substances from and by reason of this knowledge, all of which, by the way, has been acquired by experimental research. But if the chemist gives to me the very thing I want it is still impossible to proceed to apply it to practice on man before testing its action on animals inferior to man, for I have found that some of the very simplest and seemingly most innocuous of substances are most fatal.

One of the pioneers of anæsthesia with whom I had the privilege to live and work, did once introduce into practice a new, effective, and, in atomic construction, very simple anæsthetic In the course of a comparatively few administrations of this agent to man, two deaths resulted. To the end of the useful life of this, my friend, he never ceased to regret that he had not first subjected the agent to more vigorous tests of action on animals inferior to man. Once in my researches I got under observation another anæsthetic which seemed perfect. I should have introduced it into practice, had not the lesson I had learned above corrected the error. For on submitting the new agent to the required strain of experiment, I found it so fatal to animals that had I put it forward I should certainly have deepened the shadow of death on the picture of retreat of pain. Twice in the same manner I have prevented other men from introducing anæsthetics which did not bear the full test of proof of experiment on the inferior animal. The reasonable mind will take in all these practical points, and, I think, will come to the conclusion that for no application to the necessities of man and of all other animals could the lives of inferior animals be more justly applied. To kill animals for food, to apply them to works of useful labour, is not more just.

Method of Experimentation.

The method of experimentation I have pursued has taken two courses:—

(a) The subjection of animals to narcotising gases or vapours for the purpose of inducing in them anæsthetic sleep, observing the action of the narcotic through all its degrees of action, and the mode in which it destroys life when it is pushed to the point of destruction of life.

(b) The subjection of animals to local methods of abolishing pain, or, more correctly, of destroying pain in parts of the body locally, so that operations may be performed painlessly while the general consciousness remains, and without any danger at all to life.

In carrying out the first of these inquiries, the plan pursued was as follows:—A narcotising chamber was used, the precise capacity of which was determined. The chamber, made of glass and iron, was, when closed, air-tight, but it was furnished with openings through which it could be charged with the precise measures of the narcotic vapour or gas required. It was also so arranged that the temperature and dryness, and when necessary, pressure of the atmosphere within it could be moderated. Briefly, the chamber was so constructed that the action of every volatile narcotic substance could be tested in it under all known external conditions.

The animals subjected to experiment have as a rule been of two kinds—rabbits and pigeons. Rabbits have been used because when they are allowed to sleep to death in the vapour, or when they accidentally sleep to death, they are good subjects for examination after death, and tell clearly the reason of death. Pigeons have been used for two reasons: first because they succumb more easily to anæsthetics than any other animals, easier even than man; secondly because during sleep they give indications of dangerous or troublesome effects, such as rigidity and vomiting, quite as easily as man. If, therefore, a pigeon will go safely and easily through an anæsthetic sleep, the inference is fair that a man will do so; and in all cases where I have found the anæsthesia so safe and satisfactory on these animals—rabbits and pigeons—as to commend the anæsthetic which produced it, I have always proceeded to try the effect on the human subject by inhaling the anæsthetic myself until it produced the insensible sleep.

In experimenting on the animals, they have been gently introduced into the narcotic chamber from above, and as they have passed into insensibility, each of the stages of narcotism—usually four in number—have been carefully recorded by their phenomena. The facts have been tabulated in set form so as to show, per-centage of vapour diffused, time required to produce insensibility, period of each stage, muscular disturbance, state of the respiration, state of the heart pulse, change of animal temperature, and condition of the pupil. In cases of recovery from the anæsthetic, the signs and period of recovery have been recorded; in cases of death in the anæsthetic sleep, the time and mode of death whether by the heart or by the respiration, have been recorded.

I should remark that these researches have not been made at any regular times. They have been suggested by the study of some chemical substance which presented some promising qualities for the object in view. I believe no new substance of this kind has for the last twenty-five years escaped my observation.

On the animals themselves no pain can be said to have been inflicted. The worst that has happened to them has been that they have passed into deep sleep and have waked again just as a human being who has taken chloroform successfully for an operation, sleeps and wakes. Or else they have passed into sleep and from sleep into death, a mode of dissolution so serene, so painless, as to be an enviable imitation of natural euthanasia.

In the researches on local means of relieving pain, the part to be anæsthetised has been simply subjected to the action of the anæsthetic. At first I used lower animals for this method of inquiry, but owing to their comparative low sensibility they proved unsatisfactory. A mode of local anæsthesia which on a dog or rabbit seems abso-

lutely perfect may, I found, be most imperfect on a man or woman. I once thought I had established a perfect local anæsthesia by applying to animals narcotic solutions locally, in combination with a gentle continuous electric current. It seemed to me that the current caused a rapid absorption of the narcotic, or so acted with it on the minute blood-vessels as to produce contraction of them and destroy local insensibility. Under this plan I performed a number of operations on the lower animals without exciting the slightest evidence of pain. When I came to man the process broke down; some insensibility was, without doubt, produced, and seventeen operations were performed by the local plan. But the more exalted sensibility of the higher animal was not satisfied, and I learned that what would do perfectly for a dog was quite inefficient for a human being.

It is a curious episode in this research and worthy of record, that one of my scientific critics, the late Dr. Waller, a man of great genius, actually showed that he could perform on dogs without any anæsthesia at all, the same operations that I performed with this local anæsthesia, and with similar apparent freedom from pain. The result was that I continued all my after experiments on local anæsthesia, first on my own body, and then on other human subjects who required such anæsthesia for operation. All my experiments with sprays to produce insensibility by intense cold, on Dr. James Arnott's most original design were first performed in this manner, and the process was only applied to the inferior animals after it had been made perfect for the surgical purposes for which they required it. In this instance therefore man became the subject of physiological experiment for the benefit of the inferior animals as well as for his own.

Primary Results of the Experimentation with Anæsthetics.

The primary results of these experiments on different modes and processes for inducing anæsthesia may be put forward in a few sentences. They were all of them results which could not have been reached by any other line of research.

1. The experimentation has enabled me, as a physician, to keep on a level with the chemist in applying to the services of man all those agents for the relief of pain which the chemist produces. The chemical bodies of the methyl, ethyl, butyl, and amyl series with several others which have promised to be of any service have been tested, and their respective values carefully chronicled.

2. For general anæsthesia I have been enabled, by the research to add many new and useful anæsthetics. Bichloride of methylene, which has been very largely used, and which Mr. Spencer Wells invariably uses with signal success for ovariotomy, came from this research. Methylic ether, the safest anæsthetic I have yet known, was proved by this research. Methylal, another very valuable agent of the same kind, and which has to be practically applied, is another good anæsthetic added by these inquiries; while several agents tried for anæsthesia which have not answered, have been accidentally discovered to possess other and valuable curative properties. The introduction of the etherial solution of peroxide of hydrogen, an exceedingly useful remedy, and the local use of butylic alcohol for toothache, are two instances amongst many more of this kind.

3. The researches have enabled me to formulate the physiological properties of the organic bodies that produce anæsthesia, so that the value of the anæsthetic compounds may be calculated from their physical characters and composition. I have been able to show that some elements—such as chlorine—are objectionable parts of an anæsthetic agent, others favourable; that certain degrees of solubility are objectionable, others favourable; that certain vapour-densities are objectionable, others favourable. I have been able to point out a distinct theoretical standard of qualities which, being found, will yield a safe, manageable, and agreeable anæsthesia. Lastly, I may add, from an experience in the study of anæsthetics extended from the time when they were first introduced until this hour, the positive assurance that careful and steadily pursued experimental research must result in the discovery of all the laws relating to anæsthesia, and to the further discovery of an absolutely safe mode of producing it. For I have learned that no man, no animal, ever yet has died because it was rendered insensible to pain, and the deaths which have occurred have invariably been due to some property of the substance used that had no relation to the anæsthetic property—some independent bad quality which we may fairly expect science to eliminate for the benefit of man.

4. While striving to apply the results of experimentation to the advantage of the human family, I have not forgotten the inferior creation, and in nothing have I been more successful than in their behalf. For operations on animals I have been able to make the application of local anæsthesia so perfect that there is no necessity whatever that any lower animal should ever feel a pang from the knife of the operator for any external cutting operation it may have to undergo. The Society for the Prevention of Cruelty to Animals has itself published the facts of an operation, for removal of a large tumour from a horse belonging to Sir Wm. Erle, that was performed by my method of operating under ether spray while the animal stood in the stable without halter or bridle, oblivious of all pain. That fact,—one of a hundred similar,—I put forward, not as in itself peculiar, but because of the record from which it is taken. It could not have been recorded even there but for the experimentation that gave it birth.

BENJAMIN W. RICHARDSON

NOTES

HER MAJESTY has been pleased to confer on Prof. Wyville Thomson the honour of knighthood.

IT is stated that Sir C. Wyville Thomson and the members of the scientific staff of the *Challenger* will be entertained at dinner in Edinburgh on July 7. The Lord Provost has consented to take the chair.

WE notice from the official announcement in connection with the Loan Collection, that during the present week, fourteen demonstrations of apparatus were given on Monday, eleven on Tuesday, four on Wednesday and Thursday, while seven will be given on Saturday. With regard to the complaint in the *Times* as to the occasional non-attendance of the lecturers, it should be remembered that these demonstrations are given out of pure good-will by some of the most eminent and busy of the scientific men of the day, who are not always masters of their own time. The Department's arrangements are entirely dependent on the convenience of these men, and it should not therefore be blamed if its proposed programmes are not always rigidly carried out. The following arrangements have been made for future free evening Lectures on the Instruments in the Collection:—Saturday, July 1, Prof. Tyndall, F.R.S., on "Faraday's Apparatus," in the Lecture Theatre, South Kensington Museum; Monday, July 3, the Right Hon. Lyon Playfair, C.B., M.P., F.R.S., on "Air and Airs," as illustrated by the Magdeburg Hemispheres and Black's and Cavendish's Balances; Saturday, July 8, Dr. Gladstone, F.R.S., "The Work of Davy and Faraday," as illustrated by the Apparatus lent by the Royal Institution; Monday, July 10, Rev. R. Main, M.A., F.R.S., on "The Instrumental Foundations of Practical Astronomy;" Saturday, July 15, Dr. W. H. Stone on "Modes of Eliciting and Reinforcing Sound;" Monday, July 17, Mr. C. V. Walker, F.R.S., on "Galvanic Time Signals;" Saturday, July 22, Mr. W. Chandler Roberts, F.R.S.,

SCIENTIFIC SERIALS

THE current number of the *Ibis* commences with two papers on the ornithology of the Fiji Islands, by Mr. E. L. Layard, in which the following species are described:—*Platycercus taviunensis, Myiolestes macrorhynchus, M. compressirostris, Pachycephala torquata.* Additional notes on other birds are given, including *Lamprolia victoriæ.*—Mr. H. Durnford has ornithological notes from the neighbourhood of Buenos Ayres, in which the habits of the birds of the district are briefly described.—Mr. R. Ridgway writes on the genus *Helminthophaga*, precisely defining the distribution of the ten species and their specific characters.—Mr. H. E. Dresser continues his notes on Severtzoff's "Fauna of Turkestan," the species of birds most lengthily noticed being *Leptopoecile sophiæ, Anthus pratensis,* and *Lanius isabellinus,* together with *Caprimulgus pallens* and *C. arenicolor.*—Mr. F. Barratt gives ornithological notes made during trips between Bloemfontein and the Lydenburg gold-fields, figuring *Bradypterus barrati.*—Messrs. H. Seebohm and J. A. Harvie Brown continue their notes on the birds of the Lower Petchora, figuring the eggs of *Squatarola helvetica.*—Mr. J. H. Gurney continues his notes on Mr. Sharpe's "Catalogue of the Accipitres in the British Museum," devoting himself on this occasion to the American Buzzards.—Mr. P. L. Sclater gives an interesting account of the recent ornithological researches of Beccari, D'Albertis, and von Rosenberg in New Guinea, and Count Salvadori writes on two New Guinea species, *Sericulus xanthogaster* and *Xanthomelus aureus.*—Canon Tristram describes a collection of birds from New Hebrides, among which is a new species of *Porphyrio, P. aneiteumensis.*

Poggendorff's Annalen der Physik und Chemie.—Ergänzung, Band vii., Stuck 4.—We have here a valuable second memoir by M. Chwolson on the mechanism of magnetic induction, which process he seeks to explain by the supposed existence of molecular magnets that are turned by the external force in one direction. In his former paper he dealt with the case of temporary induction in soft iron; he here treats of magnetic induction in steel. The paper is in five chapters: in the first are summarised the results obtained by previous observers, those of Jamin being given with special fulness. In the second the author describes his experiments, which require a modification of Jamin's theory. Of Jamin's two laws relating to the action of positive and negative currents on permanently magnetised bars, M. Chwolson finds the first absolutely correct; the second incorrect. Jamin's mistake he considers to be in the supposition that the negative current only acts on the surface layers, leaving those below untouched; it is shown, on the contrary, that the least negative current acts on all the layers and diminishes their intensity. Then he gives a mathematical theory of induction in steel; supposed the first attempt of the kind (if Maxwell's but partly successful one be excepted). In the fourth chapter he explains, on the basis of theory, the various experimental results got by different observers; and in the fifth, shows how certain results that might *à priori* be foreseen, from the theory, have been verified.—M. Holtz has a paper on some changes of form of the Leyden battery (with a view to extending the length of spark), and its use with influence-machines; and he describes some good phenomena of discharge. The remaining papers are extracts.

Der Naturforscher, February.—In this number we may note an account of observations by M. Mallard on the velocity of inflammation in a mixture of fire-damp and air. The various mixtures were set in motion with different velocities, and that velocity at which the zone of combustion remained stationary measured the velocity sought. The highest velocity of inflammation was 0·560 metres in a second, and it occurred in a mixture of 0·108 vol. of fire-damp in one volume of the mixture. On increasing or diminishing the proportion of fire-damp, the velocity in question diminished very rapidly, becoming *nil* with a proportion of 0·077 vol. on the one hand, and 0·145 vol. on the other, below which the mixtures are neither explosive nor inflammable. It is notable that a variation of even 0·01 in the proportion of fire-damp is sufficient to convert an absolutely indifferent mixture into a highly dangerous one.—In geology there is an adverse criticism of Mr. Mallet's theory of volcanic action, by M. Roth, and an experimental inquiry by M. Hoppe-Seyler into the formation of dolomite. The latter points out that wherever, on a sea-bottom covered with chalk or limestone, eruptions of lava occur, dolomite is a necessary product, the lava supplying the temperature (which must be high), the limestone the calcium and carbonic acid, and the sea-water the magnesium.—From twenty years' observations in St. Petersburg, M. Rikatcheff draws some conclusions as to the influence of cloudiness on the daily variations of temperature.—We further note an abstract of a recent *brochure* by Prof. Lommel, on the interference of reflected light (the author developes variously a well-known experiment of Newton), and a summary of an interesting lecture by M. Löwe to the Physiological Society of Berlin, on the theory of descent.

March.—The formation of cheese has lately engaged the attention of Prof. Ferd. Cohn in connection with his researches on the lowest forms of plant life; and he has made personal observations on the manufacture, as carried on in Switzerland. The phenomena accompanying the process are thus described: The rennet contains a liquid ferment which causes coagulation of the milk; also ferment-organisms (Bacillus), which probably bring on butyric-acid fermentation, and cause the slow maturing of the cheese. It is their resting-spores that, enclosed by the dry cheese substance, resist boiling heat for a long time, and, in a suitable nutritive liquid, may afterwards develop to bacillus rods. (One of Dr. Bastian's results is thus explained.)—In a paper by M. Rosenthal, the action of the automatic nerve-centres is explained as dependent, not on some immanent property of the nerve apparatus, but on the nature of the blood. To account for the rhythmus of the movements in breathing, he supposes a constant resistance opposed to the constant excitation, and illustrates the case by supposing a vertical tube closed below by a plate which is pressed against it by a spring, while a constant stream of water flows in from above. When the liquid reaches a certain height the spring yields, and some water escapes; then the spring forces back the plate, and the process is repeated, thus giving a rhythm. From experiments made by M. Bartoli, in Italy, it is inferred that all solid and liquid substances, whatever their nature, have, in air, a damping influence on the oscillations of a magnetic needle suspended over them, and that this action depends on the air that is between the two surfaces. Among other subjects handled in this number may be mentioned those of irregularities of the sea-level (Hann), the molecules of isomeric and allotropic bodies (Smit), the physical properties of litter in woods (Ebermayer), and decomposition of albuminous matter in animal bodies (Drechsel).

SOCIETIES AND ACADEMIES

LONDON

Royal Society, May 4.—Supplementary note "On the Theory of Ventilation" (see NATURE, vol. xi. p. 296). By Francis S. B. François de Chaumont, M.D., Surgeon-Major, Army Medical Department, and Conjoint Professor of Hygiene, Army Medical School. Communicated by Prof. Stokes, Sec. R.S.

In his previous paper the author endeavoured to establish a basis for calculating the amount of fresh air necessary to keep an air-space sufficiently pure for health, taking the carbonic acid as the measure. The results showed that the mean amount of carbonic acid as respiratory impurity in air undistinguishable by the sense of smell from fresh external air was under 0·2000 per 1000 volumes. His object in the present note is to call attention to the relative effects of temperature and humidity upon the condition of air, as calculated from the same observations.

Linnean Society, June 1.—Prof. Allman, president, in the chair.—An interesting series of photographs illustrating coffee cultivation in Ceylon, an enormous banyan tree and other tropical vegetation, were shown by Mr. J. R. Jackson, of the Kew Museum; Mr. W. Bull's exhibition of several fine healthy, growing plants, and the seeds of his lately introduced *Coffea liberica* and of *C. arabica* for comparison came in most *à propos* to the above.—The Rev. G. Henslow read a paper on floral æstivations, in which, after giving the eight kinds, viz., distichous, tristichous, pentastichous, half-imbricate, imbricate proper, convolute, valvate, and open, he explained their origin, and specially dwelt upon the new term *half-imbricate*, which he applied to a very large number of cases ranging from perfect regularity to extremely irregular and zyomorphic flowers of the pea and snap-dragon. The author then showed how that, as well as the fifth and sixth kinds were successively deducible from the third or pentastichous (quincuncial) by merely shifting one edge of the *second* part *under* the adjacent edge of the *fourth* part. The author added a note on a new theory of the cruci-

ferous flower, based on a quinary type, and which, by *symmetrical reduction* (*i.e.*, the fifth part of each whorl would be suppressed) the remaining fours would, by further arrest, due to adaptations to insect agency, form the normal flower. He also disputed the tenability of *Chorisis* in the pairs of long stamens, regarding their occasional union as indicative of evolutionary advance and not retrogression; as cohesion is a subsequent stage to freedom, except in the rare cases of atavism indicated by solution and dialysis. The author called in question the justness of Pfeffer's view of the corolla of primula, being an outgrowth of the Andrœcium, by showing (*a*) the position of the stamens to be explained by the staminodia of Samolus, (*b*) that the corolla appearing subsequent to the stamens is no anomaly, (*c*) that the fibro-vascular bundles are ten in number, of which five are intermediate, and (*d*) that phyllotactical æstivation were those of true leaves; so that all these facts conspired to render the theory untenable. Mr. J. G. Baker read a paper on a collection of ferns made by Mr. Wm. Pool in the interior of Madagascar. Altogether 114 species have been obtained, of which fifteen are entirely new and twenty-eight prove to be varieties of already known forms. Some examples, *e.g.*, *Asplenium trichomanes*, *Nephrodium felix-mas*, and *Aspidium aculeatum*, are thoroughly temperate types.—Mr. Francis Darwin read an account of some researches of his on glandular bodies on *Acacia sphærocephala* and *Cecropia peltata*, serving as food for ants. The structures in question were discovered by Mr Belt (Nicaragua), and subsequently further observations made by Fritz Muller (Brazil), while Mr. Darwin has more particularly entered into their minute composition. In Acacia they are of two kinds (*a*) nectar-secreting glands situate at the base of the petiole, (*b*) small, somewhat flattened, pear-shaped bodies, which tip six or seven of the lowermost leaflets of the bipinnate leaves. In Cecropia cylindrical bodies are developed in flat cushions at the base of the leaf-stalk. Mr. Darwin shows the microscopical structure of all of these to be homologous in kind, cellular, protoplasm, and containing oil globules. He infers, moreover, they bear a relation to the serration-glands of Reinke, in certain cases afterwards being converted into stores of nutriment, which undoubtedly the ants live on, and in their turn protect the trees from the ravages of the leaf-cutting ants.—A notice of the lichens of Madagascar collected by Mr. W. Pool, by the Rev. J. M. Cerombie, was taken as read.—Prof. Wyville Thomson, of the *Challenger* Expedition, addressed the meeting, giving the results of two communications by him; one on new living Crinoids belong to the Apiocrinedæ, the other on some peculiarities in the mode of propagation of certain Echinoderms of the Southern Seas.

Royal Astronomical Society, June 9.—William Huggins, D.C.L., president, in the chair. A paper by Prof. Simon Newcomb was read on a hitherto unnoticed apparent inequality in the longitude of the moon. The inequality was, it appeared, brought to light in the course of an investigation which has recently been made by Prof. Newcomb, of the corrections to be applied to Hansen's "Tables de la lune," in order that they may be used for the determination of the longitudes of the transit of Venus stations. Prof. Newcomb set himself to compare the places derived from Hansen's Tables with the series of lunar observations made at Greenwich and Washington between the years 1862 and 1874. The residual errors of the moon's place showed a systematic inequality which could not be got rid of by any new assumption as to the value of the corrections of the lunar elements. There can be no serious doubt about the existence of the inequality, because both the Greenwich and Washington observations agree in showing it, and a close investigation shows that the errors are periodic and depend upon the moon's longitude. In order to make the investigation more complete, Prof. Newcomb has determined the corrections for the years 1847 to 1858, for which period the residual errors of Hansen's Tables are given in the Greenwich observations of 1859. A table of the resulting corrections is given in the paper, and it appears that the period of the chief term of the new inequality is 16½ years with a probable error of half a year. The corresponding period of the inequality in longitude is 27·4304 days ∓ 0·0040 days, and there is a large preponderance of probability against the real period being less than 27·42 days, or more than 27·44 days. No known term in the moon's longitude falls within these limits. The moon's sidereal period is 27·32 days and the anomalistic period is 27·55 days, so that the new term falls half way between the two. The non-accordance of this period with any term heretofore sought for, is the probable reason why this term has not before been noticed; a term if unknown would not be remarked unless its value was such as visibly to effect the individual comparison of theory with observation, and Hansen's tables as corrected are the first of which the residual errors are so small that a term of 1″·5 would be remarked in the comparison with observations. Prof. Adams said that he was at a loss to imagine what the cause of this inequality can be, he was rather inclined to suppose that it may have something to do with the effect of the figure of the earth on the motion of the moon, but this was only an idea thrown out on the spur of the moment.—Lord Lindsay exhibited an adaptation of the ordinary altazimuth instrument designed to give a rough equatorial motion; to the base of the altazimuth pillar is fixed an iron bar, through a hole in which a [illegible] or wire is attached to the object-glass end of the telescope; that the only adjustments that are necessary are that the horizontal hole shall be placed approximately north and south, and the distance from the base of the altazimuth pillar to the hole in the bar through which the string passes shall be equal to the height of the pillar into the cotangent of the latitude of the place of observation.—Mr. Plumber read a paper on photometric experiments upon the light of Venus. By comparing the shadow of a wire cast by the light of the planet with the shadow of a similar wire cast by a candle at a known distance, and again by comparing the light of the candle with the light of the full moon, he came to the conclusion that the light of Venus at its greatest brilliancy was equal to $\frac{1}{799 \cdot 5}$ of the brightness of the full moon, and by a similar method found that the light of Jupiter at mean opposition was equal to $\frac{1}{6430}$ of the light of the mean full moon.

Chemical Society, June 15, Dr. J. H. Gladstone, F.R.S., vice-president, in the chair.—A large number of communications were read, this being the last meeting of the season. The first paper, by Prof. Dewar, entitled "Chemical Studies," was chiefly devoted to an account of several interesting lecture experiments.—Dr. H. E. Armstrong then gave a short account of his elaborate researches on the reduction of nitric acid and on the oxides of nitrogen, part i., on the gases evolved by the action of metals on nitric acid, made in conjunction with Mr. Acworth.—Mr. C. T. Kingsett then read a paper on the composition and formula of an alkaloid from Jaborandi.—There were also papers on the simultaneous action of iodine and aluminium on ether and compound ethers, by Dr. J. H. Gladstone and Mr. A. Tribe; on compounds of antimony pentachloride with alcohols and with ethers, by Mr. W. C. Williams; on the volatility of barium, strontium, and calcium, by Prof. J. W. Mallet; on the action of chlorine on acetamide, by Dr. E. W. Prevost; note on the perbromates, by Mr. M. M. P. Muir, and a communication on a new and convenient form of areometer for clinical use, by Dr. J. G. Blackley.

Geological Society, June 7.—Prof. P. M. Duncan, F.R.S., president, in the chair.—John Thos. Atkinson, Edmund Clark, Frederick Derry, Walter S. Gervis, Thos. Jones, Baldwin Latham, and Edward Sewell, were elected Fellows of the Society.—On the British fossil cretaceous birds, by Prof. H. G. Seeley, F.L.S. In this paper the author gave an account of the remains of birds which have been collected from the Cambridge Upper Greensand. The bones are so fragmentary that the size of the animal can only be given roughly as similar to that of the Diver, but with a shorter neck. The affinities of the animal are strongest with *Colymbus*. It also closely resembles Prof. Marsh's cretaceous genus *Hesperornis*, and like that genus may be supposed to have had teeth. The species were described as *Enaliornis Barretti* and *E. Sedgwicki*. Some bones were also described thought to indicate birds in which the extremities of the bones remained unossified throughout life.—On two chimæroid jaws from the Lower Greensand of New Zealand, by E. T. Newton, F.G.S., of H.M. Geological Survey. The two jaws which were the subject of this communication form part of the collection of fossils from the Lower Greensand of New Zealand deposited in the British Museum by Dr. Hector. One of the specimens, a right mandible, was referred by the author to *Ischyodus brevirostris*, Ag., a species from the Gault of Folkestone, hitherto known only by name, no description or figure of it having been as yet published. The second specimen, a small right maxilla, possessing but one tooth, and this of a peculiar form, was compared with the corresponding form in *Ischyodus*, *Edaphodon*, *Elasmodus*, *Ganodus*, *Chimæra*, and *Callorhynchus*. Reasons were given for

believing that it differed generically from all other known forms of Chimæroid jaws; and the author therefore proposed to call it, in allusion to the form of the tooth, *Upsilodus Hutori*.—On a bone-bed in the Lower Coal-measures, with an enumeration of the fish-remains of which it is principally composed, by J. W. Davis, F.L.S. In this paper the author described a thin bed composed chiefly of remains of fishes. which rests immediately upon the "Better-bed coal" of the Lower Coal-measures in Yorkshire.—Note on a species of Foraminifera from the Carboniferous formation of Sumatra, by M. Jules Huguenin. Communicated by Prof. Ramsay, F.R.S., V.P.G.S. The author described some globular Foraminifera, belonging or allied to *Fusulina*, from a carboniferous deposit containing *Producti* and *Phillipsiæ*, which occurs north-[illegible] Padang and south of the lake of Singkarak in Sumatra. [illegible], and [illegible]thor described the structure of these fossils, which he [illegible] *C. aren*[illegible] with *Fusulina cylindrica* and *F. depressa*, and arrived [illegible] [illegible]clusion that they belong to a new genus, to which [illegible] North American *Fusulina robusta* also belongs.—On t[illegible] Triassic rocks of Somerset and Devon, by W. A. E. Usher, F.G.S. The author stated that the Trias of Devon and Somerset was divisible into three groups, occupying distinct areas. The first lies north of the Mendip Hills, where the Trias is thinnest and assumes its simplest characters, consisting of marls and Dolomitic conglomerate. The second area embraces the country south of the Polden Hills as far as a north and south line through Taunton. The chief portion of the Trias in this area, as in the northern, consists of marls. The third area, bounded on the north by the Bristol Channel, on the south by the English Channel, on the east by the Blackdown range, and on the west by [illegible] Culm and Devonian highlands, presents the most complex r[illegible]ons of the Trias in the south-western counties.

Victoria (Philosophical) Institute, June 19.—A paper by Prof. Morris, M.D., of Michigan University, on the theory of unconscious intelligence as opposed to theism, was read. The paper discussed the theories which have been put forward on the subject. The professor laid down the proposition that consciousness and intelligence imply one another, and that, therefore, "unconscious intelligence" is a self-contradictory phrase.

PARIS

Academy of Sciences, June 12.—Vice-Admiral Paris in the chair.—The following papers were read:—Experimental critique on Glycemia (continued). Physico-chemical and physiological conditions to be observed in searching for sugar in the blood, by M. Cl. Bernard. The sugar found normally in blood of animals ranks among glycoses. M. Bernard shows how its properties may be demonstrated after coagulation of the blood, by superheated steam, by alcohol, or by sulphate of soda. He then details his mode of finding the amount of sugar.—On the absorption of free and pure nitrogen and hydrogen by organic matters, by M. Berthelot. White filter paper, slightly moist, placed in pure nitrogen, under influence of the effluve or silent discharge, absorbs a considerable quantity in eight or ten hours. Oxygen does not hinder this (in 100 vols. air, 2·9 hundredths of nitrogen and 7·0 of oxygen were absorbed in about eight hours). Hydrogen is absorbed even more rapidly than nitrogen by benzene, terebenthene, acetylene, &c.—On the formation and the decomposition of binary compounds by the electric effluve, by M. Berthelot. In principle the reactions are the same as those with the spark, but the longer duration of the spark and the heating it produces are adverse to the formation of condensed products, such as arise under the effluve.—Presentation of solar photographs of large dimensions, by M. Janssen. In these the disc is 22 centimetres in diameter, yet there is great distinctness. M. Cornu hopes shortly to have photographs from the focus of a telescope of 36 centimetres aperture.—On electric transmissions through the ground, by M. du Moncel. From experiments he shows how unequal moisture about the electrodes, unequal heating of these, and unequal size, are physical causes which intervene, more or less, causing variations in intensity of currents transmitted through the ground. A general conclusion is, that it is not advantageous to interpose earth in a circuit unless when its resistance exceeds 10 or 15 kilometres of telegraph wire.—On some new experiments made with Crookes's radiometer, by M. Ledieu. In the first experiment rotation was obtained from a beam of luminous rays falling parallel to the axis (though less rapid than when it falls at right angles). In the second, the two sides of the vanes were kept bright; and here the vanes moved as if repelled by the luminous ray meeting them. (The ray should be made to strike the vane next the light at a small angle, and the two opposite vanes, with reference to the plane of the ray and the axis, be shaded by a screen. The place should be quite dark.)—On amber, by M. Reboux.—On the law of Dulong and Petit, by M. Terreil. The product of specific heat by chemical equivalent is a constant, provided all the bodies are taken with the same gaseous volume, and before any condensation. The specific heat of simple bodies, taken with the same volume and gaseous state, is inversely proportional to their chemical equivalents; so is that of compound bodies, and it is proportional to the condensation of the gaseous volumes of the constituent simple bodies in combining. Simple or compound bodies which have lost the gaseous state have a specific heat double that which they have in this state.—Letter to M. Dumas on Phylloxera, by M. Fatio. The cycle of metamorphoses may, in certain circumstances, occur entirely under ground without intervention of the perfect winged form.—On the employment of sulphide of carbon against Phylloxera, by M. Allies.—Another on the same subject, by M. Marion.—On the pantanemone, an apparatus acting in all winds, without orientation and without reduction of surfaces, by M. Sanderson.—Ephemerides of the planet (103) Hera, for the opposition of 1877, by M. Leveau.—On the presence of magnesium in the sun's limb, by M. Tacchini. The magnesium gains in intensity and elevation where the flames of the chromosphere present most vivacity. While there is at present a minimum of spots, protuberances, hydrogenic clouds, and metallic eruptions, the circulation of magnesium still retains a certain energy capable of rising to a maximum as in previous years.—Phenomena of electric oscillation, by M. Mouton.—On the propylenic chlorhydrines and the law of addition of hypochlorous acid, by M. Henry.—Elementary analysis of electrolytic aniline black, by M. Goppelsrœder.—On anthraflavone and an accessory product of the manufacture of artificial alizarine, by M. Rosenstiehl.—On the internal membrane of a chicken's gizzard as an osmotic partition, by M. Carlet. Interposed between water and alcohol in the normal conditions of osmose, this membrane is always traversed by a dominating current from the water to the alcohol; it is therefore not (as generally supposed) an exception among animal membranes.

VIENNA

Imperial Academy of Sciences, Feb. 17.—The following (among other) papers were read:—Further observations on the formation of a rational space curve of the fourth order, on a conical section, by M. Weyr.—On the distribution of the colouring matter in ovules during the process of division, by M. Schenk. The ovaries and testicles of *Echinus saxatilis* are commonly yellowish, but some species have reddish violet ovaries; M. Schenk studies the changes wrought by artificial fecundation of the ovules in these latter with sperma from the yellow testicles.

CONTENTS

THURSDAY, JULY 6, 1876

A PHYSICAL SCIENCE INSTITUTE

PROBABLY the present generation knows little of the conditions under which the great exhibition of 1851 was organised, or of the important results which followed it. After clearing all the expenses of that enterprise, a large surplus remained, to administer which a Royal Charter was granted to the Commissioners who managed the Exhibition. Since 1852 the Commissioners have held numerous meetings, and quietly done a large amount of work from which the nation has reaped great benefit. Much of the success of the various departments connected with the South Kensington Museum is due to the help they have been able to give, and now they propose a scheme whereby a large proportion of the property at their disposal will be allotted for the benefit of science and art. The Commissioners recently held a meeting, under the presidency of the Prince of Wales, at which their Special Committee reported on various schemes for making use of their funds and property.

The Commissioners started with a clear capital of 186,000*l*. They have given to the Government, for the use of the South Kensington Museum, property valued at 14,000*l*., and 60,000*l*. in land. They have sold to the Government, at half the value, land for the Natural History Museum, worth 240,000*l*. They have given the site of the Royal Albert Hall, worth 60,000*l*., and retain property in it to the extent of 80 000*l*. They have invested 100,000*l*. in the galleries lent to the India Museum and Science Loan Exhibition. Notwithstanding these very considerable contributions, the Commissioners still possess out of the Kensington Gore estate, which they purchased with the surplus funds of the 1851 enterprise, landed property of very great value. We believe that the whole of the site of the International Exhibition buildings, including the Horticultural Gardens, and some adjacent properties are in the trust of the Commissioners. Five schemes have been thought of for the utilisation of this valuable property. By one of these the Commissioners could realise one million sterling, and yet retain a square of ten or twelve acres in the centre of their property. But this they do not think of adopting. The one which they seem to regard most favourably is to lease or sell the ground outside the arcades, called the East and West Annexes, and retain the Horticultural Gardens and Exhibition Buildings, by which means they would realise upwards of 350,000*l*., free from all liabilities. Whichever scheme is adopted—and the Commissioners seem to think the time is ripe for making the best of their trust in "the interests of science and art"—a very large sum will be at their disposal.

Various objects, all in accordance with the purpose for which they were originally appointed, seem to have suggested themselves to the Commissioners for the appropriation of these funds. Scholarships in science and art, it is suggested, might be founded in connection with central institutions and provincial colleges of science and art, such as those at Manchester, Birmingham, Bristol, Leeds, and elsewhere. It would be a great benefit, it is thought, to these new institutions if their more promising students could be brought up to the laboratories of chemistry, physics, and biology, which are in active work at South Kensington. A portion of the funds might also, it is thought, be devoted to the promotion of museums of science and art throughout the country, and in making grants in aid of the British Section at International Exhibitions; also in supplying several crying wants in connection with the South Kensington Museum, and erecting other buildings on the estate to be devoted to science and art.

The Commissioners are naturally anxious for the welfare of their own child, the South Kensington Museum, and for the proper exhibition of the treasures it contains, and the proper housing of its educational and other libraries. This has engaged much of their attention, more especially as the executors of the late Mr. Dyce insist on the carrying out of the provisions of his will with regard to the display of his bequest. Since the subject, however, has been under the consideration of the Commissioners, Government has made a grant of 80,000*l*. for the purposes of Art, part of which will, no doubt, be devoted to the proper allocation of the Dyce and other collections, and to some of the other purposes concerning which the Commissioners are naturally anxious. Had they been aware of this grant, no doubt they would have spoken more fully and decidedly of another scheme which appears to have come under their consideration.

The scheme to which we refer was briefly described by Mr. Cross recently in the House of Commons, and has reference to the establishment of "a museum and scientific institute, which would comprise a library of works in science and art, for the use of students at South Kensington, and public examination rooms." From the way in which the library is here mentioned we may consider that it is a matter of secondary importance in the eyes of the Commissioners, and that the main idea is to build a museum and laboratory. We confess we cannot see the immediate appropriateness of attaching a library to a laboratory and museum of this kind. At present no library of science exists, and there will be a library attached to the Natural History Museum which is now being erected on the Commissioners' grounds, and there are various places in London where the best works and serials in all departments of science can be easily consulted. There is at least no pressing need at present for a science library, while the necessity for the organisation of a laboratory and museum was never more urgent. It is known that if only a suitable receptacle were provided, many of those who have contributed to the Loan Collection are willing to leave their apparatus permanently as the nucleus of an English Conservatoire des Arts et Métiers. No better opportunity could be afforded for the commencement of a science museum; but if the Commissioners do not resolve without delay to carry out the scheme that has apparently been engaging their attention, a golden opportunity will be lost that is not likely to occur again soon.

As to the proposal to provide rooms in the Science Museum for examinations in connection with the Science and Art Department, we think the Commissioners would be doing a quite unnecessary and rather mischievous thing in carrying out such a proposal. Government has started these examinations, and is no doubt quite prepared to provide examination-rooms for itself. I

needs no leading in this matter, though it certainly does need encouragement to take under its wing a science museum and laboratory. This then it seems to us ought to be the first care of the Commissioners, leaving the examination rooms out of the reckoning, while the library can easily afford to wait for future consideration. If the idea of a library is brought too prominently to the front, we fear the building will come to be known by this and no other name, and come in the end to be mainly, if not only, what its name purports. We believe the Commissioners could spare 100,000*l*. for a Science Museum; and we are sure the great success which has attended the Loan Collection will tend to confirm them in their intentions, and induce them without delay to set about providing a permanent successor. We have no doubt that the Commissioners are quite alive to the value of a Physical Science Museum and Laboratory, and feel strongly the great need there is in this country for such an institution. They have on the whole done their work conscientiously and well, and South Kensington testifies to the highly important and beneficial results which they have accomplished. By erecting an institution for the promotion of physical science, they will show their anxiety to make their work complete in all the departments with which they have had to deal. Twenty years ago they started the Museum of Art at Kensington; if twenty years hence a Museum of Science has made equal progress, the nation will have reason to congratulate itself on the result, and be grateful to the Commissioners for the faithfulness with which they have done their work.

WHEWELL'S WRITINGS AND CORRESPONDENCE

William Whewell, D.D., Master of Trinity College, Cambridge. An Account of his Writings, with Selections from his Literary and Scientific Correspondence. By I. Todhunter, M.A., F.R.S., Honorary Fellow of St. John's College. (London: Macmillan and Co., 1876.)

WE frequently hear the complaint that as the boundaries of science are widened its cultivators become less of philosophers and more of specialists, each confining himself with increasing exclusiveness to the area with which he is familiar. This is probably an inevitable result of the development of science, which has made it impossible for any one man to acquire a thorough knowledge of the whole, while each of its sub-divisions is now large enough to afford occupation for the useful work of a lifetime. The ablest cultivators of science are agreed that the student, in order to make the most of his powers, should ascertain in what field of science these powers are most available, and that he should then confine his investigations to this field, making use of other parts of science only in so far as they bear upon his special subject.

Accordingly we find that Dr. Whewell, in his article in the "Encyclopædia Metropolitana," on "Archimedes and Greek Mathematics," says of Eratosthenes, who, like himself, was philologer, geometer, astronomer, poet, and antiquary: "It is seldom that one person attempts to master so many subjects without incurring the charge and perhaps the danger of being superficial."

It is probably on account of the number and diversity of the kinds of intellectual work in which Dr. Whewell attained eminence that his name is most widely known. Of his actual performances the "History" and the "Philosophy of the Inductive Sciences" are the most characteristic, and this because his practical acquaintance with a certain part of his great subject enabled him the better to deal with those parts which he had studied only in books, and to describe their relations in a more intelligent manner than those authors who have devoted themselves entirely to the general aspect of human knowledge without being actual workers in any particular department of it.

But the chief characteristic of Dr. Whewell's intellectual life seems to have been the energy and perseverance with which he pursued the development of each of the great ideas which had in the course of his life presented itself to him. Of these ideas some might be greater than others, but all were large.

The special pursuit, therefore, to which he devoted himself was the elaboration and the expression of the ideas appropriate to different branches of knowledge. The discovery of a new fact, the invention of a theory, the solution of a problem, the filling up of a gap in an existing science, were interesting to him not so much for their own sake as additions to the general stock of knowledge, as for their illustrative value as characteristic instances of the processes by which all human knowledge is developed.

To watch the first germ of an appropriate idea as it was developed either in his own mind or in the writings of the founders of the sciences, to frame appropriate and scientific words in which the idea might be expressed and then to construct a treatise in which the idea should be largely developed, and the appropriate words copiously exemplified—such seems to have been the natural channe of his intellectual activity in whatever direction it over flowed. When any of his great works had reached this stage he prepared himself for some other labour, and if new editions of his work were called for, the alterations whicl he introduced often rather tended to destroy than to com plete the unity of the original plan.

Mr. Todhunter has given us an exhaustive account o Dr. Whewell's writings and scientific work, and in this w may easily trace the leading ideas which he successivel inculcated as a writer. We can only share Mr. Tod hunter's regret that it is only as a writer that he appear in this book, and it is to be hoped that the promise account of his complete life as a man may enable us t form a fuller conception of the individuality and unity of hi character, which it is hard to gather from the multifariou collection of his books.

Dr. Whewell first appears before us as the author of long series of text-books on Mechanics. His position a a tutor of his College, and the interest which he took i University education, may have induced him to spen more time in the composition of elementary treatises tha would otherwise have been congenial to him, but in tl prefaces to the different editions, as well as in the intr ductory chapters of each treatise, he shows that sense the intellectual and educational value of the study of fir principles which distinguishes all his writings. It manifest from his other writings, that the composition these text-books, involving as it did a thorough study the fundamental science of Dynamics, was a most app

priate training for his subsequent labours in the survey of the sciences in their widest extent.

"It has always appeared to me," says Mr. Todhunter, "that Mr. Whewell would have been of great benefit to students if he had undertaken a critical revision of the technical language of Mechanics. This language was formed to a great extent by the early writers at an epoch when the subject was imperfectly understood, and many terms were used without well-defined meanings. Gradually the language has been improved, but it is still open to objection."

In after years, when his authority in scientific terminology was widely recognised, we find Faraday, Lyell, and others applying to him for appropriate expressions for the subject-matter of their discoveries, and receiving in reply systems of scientific terms which have not only held their place in technical treatises, but are gradually becoming familiar to the ordinary reader.

"Is it not true," Dr. Whewell asks in his Address to the Geological Society, "in our science as in all others, that a technical phraseology is real wealth, because it puts in our hands a vast treasure of foregone generalisations?"

Perhaps, however, he felt it less difficult to induce scientific men to adopt a new term for a new idea than to persuade the students and teachers of a University to alter the phraseology of a time-honoured study.

But even in the elementary treatment of Dynamics, if we compare the text-books of different dates, we cannot fail to recognise a marked progress. Those by Dr. Whewell were far in advance of any former text-books as regards logical coherence and scientific accuracy, and if many of those which have been published since have fallen behind in these respects, most of them have introduced some slight improvement in terminology which has not been allowed to be lost.

Dr. Whewell's opinion with respect to the evidence of the fundamental doctrines of mechanics is repeatedly inculcated in his writings. He considered that experiment was necessary in order to suggest these truths to the mind, but that the doctrine when once fairly set before the mind is apprehended by it as strictly true, the accuracy of the doctrine being in no way dependent on the accuracy of observation of the result of the experiment.

He therefore regarded experiments on the laws of motion as illustrative experiments, meant to make us familiar with the general aspect of certain phenomena, and not as experiments of research from which the results are to be deduced by careful measurement and calculation.

Thus experiments on the fall of bodies may be regarded as experiments of research into the laws of gravity. We find by careful measurements of times and distances that the intensity of the force of gravity is the same whatever be the motion of the body on which it acts. We also ascertain the direction and magnitude of this force on different bodies and in different places. All this can only be done by careful measurement, and the results are affected by all the errors of observation to which we are liable.

The same experiments may be also taken as illustrations of the laws of motion. The performance of the experiments tends to make us familiar with these laws, and to impress them on our minds. But the laws of motion cannot be proved to be accurate by a comparison of the observations which we make, for it is only by taking the laws for granted that we have any basis for our calculations. We may ascertain, no doubt, by experiment, that the acceleration of a body acted on by gravity is the same whatever be the motion of that body, but this does not prove that a constant force produces a constant acceleration, but only that gravity is a force, the intensity of which does not depend on the velocity of the body on which it acts.

The truth of Dr. Whewell's principle is curiously illustrated by a case in which he persistently contradicted it. In a paper communicated to the Philosophical Society of Cambridge, and reprinted at the end of his "Philosophy of the Inductive Sciences," Dr. Whewell conceived that he had proved, *à priori*, that all matter must be heavy. He was well acquainted with the history of the establishment of the law of gravitation, and knew that it was only by careful experiments and observations that Newton ascertained that the effect of gravitation on two equal masses is the same whatever be the chemical nature of the bodies, but in spite of this he maintained that it is contrary not only to observation but to reason, that any body should be repelled instead of attracted by another, whereas it is a matter of daily experience, that any two bodies when they are brought near enough, repel each other.

The fact seems to be that, finding the word weight employed in ordinary language to denote the quantity of matter in a body, though in scientific language it denotes the tendency of that body to move downwards, and at the same time supposing that the word mass in its scientific sense was not yet sufficiently established to be used without danger in ordinary language, Dr. Whewell endeavoured to make the word weight carry the meaning of the word mass. Thus he tells us that "the weight of the whole compound must be equal to the weights of the separate elements."

On this Mr. Todhunter very properly observes:—

"Of course there is no practical uncertainty as to this principle; but Dr. Whewell seems to allow his readers to imagine that it is of the same nature as the axiom that 'two straight lines cannot inclose a space.' There is, however, a wide difference between them, depending on a fact which Dr. Whewell has himself recognised in another place (see vol. i., p. 224). The truth is, that *strictly* speaking the weight of the whole compound is not equal to the weight of the separate elements; for the weight depends upon the position of the compound particles, and in general by altering the position of the particles, the resultant effect which we call weight is altered, though it may be to an inappreciable extent."

It is evident that what Dr. Whewell should have said was: "The mass of the whole compound must be equal to the sum of the masses of the separate elements." This statement all would admit to be strictly true, and yet not a single experiment has ever been made in order to verify it. All chemical measurements are made by comparing the weights of bodies, and not by comparing the forces required to produce given changes of motion in the bodies; and as we have just been reminded by Mr. Todhunter, the method of comparing quantities of matter by weighing them is not strictly correct.

Thus, then, we are led by experiments which are not only liable to error, but which are to a certain extent erroneous in principle, to a statement which is universally

acknowledged to be strictly true. Our conviction of its truth must therefore rest on some deeper foundation than the experiments which suggested it to our minds. The belief in and the search for such foundations is, I think, the most characteristic feature of all Dr. Whewell's work.

J. CLERK MAXWELL

GOULD'S BIRDS OF NEW GUINEA

The Birds of New Guinea and the Adjacent Papuan Islands, including any new Species that may be Discovered in Australia. By John Gould, F.R.S., &c. Parts I., II., and III. (London: Published by the Author, 1875 76.)

NOT long ago we had the pleasure of recording in these columns the completion of one of Mr. Gould's great series of illustrated works on ornithology. We have now to notice the commencement of another work belonging to the same category, of not less importance, on the origin of which we propose to say a few words. The "Birds of Australia" must be known to most of our scientific readers as one of the most important ornithological works ever produced in this or any other country. Defects it has, no doubt—nothing is perfect in this world—but, whereas before its existence the birds of that great continent were almost unknown to naturalists, the termination of Mr. Gould's labours left us with such a history of the feathered inhabitants of this portion of the globe as hardly any other country at that time possessed. Some years after the completion of his "Birds of Australia," Mr. Gould issued the first number of a supplement to the same work, undertaken for the purpose of illustrating the new species discovered by his various agents and correspondents, as new portions of Australian territory were explored. This was completed in 1869, and gave us an account of 81 species, in addition to 600 already included in the original "Birds of Australia." The work of which the two first numbers are now before us - though a different title is given to it—is, in fact, a second supplement to the "Birds of Australia." New Guinea, as is now well understood by naturalists, in spite of a certain amount of idiosyncrasy, belongs essentially to the same fauna as Australia. Long ago it was known that many peculiarities are common to the animal and vegetable products of these two countries. Since Northern Australia has been explored, and further investigation made of the rich fauna of New Guinea, the many points of contact between the natural productions of these two lands have been greatly augmented, and there can be little question that we have in New Guinea an exaggerated reproduction of many of the chief peculiarities of the Australian type. Looking to the great interest that is now more than ever attaching itself to the products of New Guinea, Mr. Gould has very naturally determined to combine his illustrations of the many wonderful birds of that country with the new additions that he still continues to receive from Australia, and this is, in fact, the object of the present work.

The great feature in the ornithology of New Guinea is, as is well known, the Paradise-Birds, which are mostly confined to that country and the adjoining islands, though some of the members extend far into North Eastern Australia. The splendid metallic colouring of these birds and the ornamental tufts and plumes that adorn the adult males, afford welcome subjects to the artist's pencil, and are naturally objects on which Mr. Gould is desirous of showing his habitual skill. We have not, therefore, to turn over many leaves of his first number, before we come across representations of two of the finest members of this group, namely the Six-plumed Paradise Bird, known to naturalists since the days of Linnæus, and D'Albertis' Paradise Bird, one of the most recent additions to this remarkable group. In the second number Mr. Gould gives us figures of the three species of *Diphyllodes*, another remarkable member of the same family. Some of the splendid parrots of New Guinea are likewise depicted.

In the third part of his work, which has only been issued within these last few days, further illustrations of the magnificent group of Paradise-Birds are given. The singular species of *Diphyllodes*, so remarkable for its bare head, which the late Prince Charles Bonaparte, in his democratic ardour, dedicated to the Republic, is among the most striking forms yet discovered even in this wonderful group, and both sexes are admirably figured in the present number. Although originally described from a single imperfect specimen, this striking bird has recently been discovered by Dr. Bernstein living in the islands of Waigiou and Botanta, and no less than ten specimens obtained by this zealous but unfortunate explorer ornament the gallery of the Leyden Museum. The King Bird of Paradise (*Cicinnurus regius*) is another species selected by Mr. Gould for illustration in the present number. Although known to us since the last century, it is only of late years that perfect specimens have reached the collections of Europe. Our countryman, Mr. Wallace, was one of the first naturalists to observe it in its native forests, and his eloquent account of the specimens obtained by him in Aru will be known to many of our readers. Still more recently, the naturalists in the employ of the Leyden Museum and the Italian explorers D'Albertis and Beccari have sent to Europe a large number of specimens of it. Five charming parrots of the most brilliant and strongly contrasted colours, several of which are hitherto unfigured, are likewise depicted in Mr. Gould's third number.

The part terminates with figures of two recent additions to the Avifauna of Australia. Of these the two named *Sternula placens* is perhaps rather a doubtful species as regards its novelty to science, though doubtless new to the Australian list. The second *Glyciphila subfasciata* is one of Mr. E. P. Ramsay's interesting discoveries in Northern Queensland, and is one of the smallest and most plainly coloured of the great and characteristic of the Australian family of Honey-eaters.

In concluding our notice of this important work, we may venture to say that those who are acquainted with the author's failing health, cannot but admire the spirit which he has displayed in commencing it, while every one will, we are sure, heartily join with us in wishing him complete recovery and a successful accomplishment of his arduous task. When one of our Italian friends has recently described fifty-two new species of Papuan birds in a single memoir, even Mr. Gould's well-known energy will have to exert itself considerably in order to keep up with what is going on.

OUR BOOK SHELF

Famines in India; their Causes and possible Prevention. Being the Cambridge Le Bas Prize Essay, 1875. By A. Lukyn Williams, B.A. (London: Henry S. King and Co., 1876.)

WE have in this prize essay a very creditable digest of a mass of blue books touching on a subject of the greatest importance to India, and to ourselves. Mr. Williams has first sought to interest his readers by recalling famines nearer home and their dreadful consequences; he has then divided his subject into two parts, the first occupied with the causes, the second with the possible prevention of famines in India.

The chief causes producing a failure of crops are to be found in the land having too little or too much water,—in the failure of the seasonal rains, or in floods from overcharged rivers; to which must be added the wants due to the difficulty of conveying food from places where it is abundant to those where its production has been destroyed. There can be little doubt as to the common causes of famines in India; the important question is how they are to be prevented.

Is it possible to be prepared for a failure of the seasonal rains, that is, can we foresee by our present knowledge, that a year, half a year, or even three months hence there will certainly be a great deficiency of rain over a given district or country? This, we have to confess, is at present beyond our power. Meteorology cannot yet be called a science; it is a series of fragmentary facts; a mass of undigested observations; a groping after laws through false hypotheses which have gained their position through celebrated names. As long as men like Galileo were satisfied with the hypothesis that nature abhorred a vacuum, all progress in hydrostatics was impossible. Although we have got over that, the spirit which kept Aristotle alive is still above ground, and meteorology will scarcely advance unless facts are studied independently of the views of any master as to their causes. What hereafter may be possible in the way of prediction is too wide a subject for this notice.

Failing the foreknowledge required to be prepared for the want of rain, there remains the very practical process of being provided with water, through canals and aqueducts connected with the many perennial sources of India. Mr. Williams appears to have referred little to the views of Sir Arthur Cotton on this part of the subject, though these are of the highest value. When both rain and aqueducts are wanting, good means of communication with more favoured districts are essential (these are indeed essential in any case), great central railways are required for our hold, and proper government of the empire, but these are too costly to satisfy for many long years the real requirements of such a people and of such a country. Wherever they can be made, canals, which serve as great lines of communication and feeders of aqueducts for irrigation, are apparently best suited to the present wants of India: these, with large reservoirs, which could frequently be constructed at moderate expense, would diminish to a great extent the possibility of famine.

That forests retard the discharge into rivers of the fallen rain, and diminish the height of floods, is a fact now so well known that the planting of trees and the preservations of woods, especially on steep slopes, has been recognised as essential to the protection of every land subject to inundations. Mr. Williams has treated of these and many other matters, including the improvement of agriculture and land tenure, in a way which shows he has mastered the reports of several highly distinguished officers who have studied these questions on the spot; and the essay will give readers interested in its subject a very satisfactory idea of the facts connected with it.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Lectures on Meteorology

MOST people conversant with the subject will agree with "Spes" (vol. xiii., p. 169) that meteorology should now be considered as much a separate science as mineralogy or geology, and be taught as such; but I would suggest whether without waiting for the foundation of special chairs in the colleges, immediate steps might not be taken with advantage to bring it before the class of persons not usually to be found in colleges, to whom it is of essential importance, by means of the Science and Art Department Organisation.

Physical Geography, which may be considered as a somewhat kindred science, is, I believe, one of the most popular amongst the candidates for the South Kensington certificates, and by the directory for 1875 it appears that in that year this subject was taught in 686 classes to 17,720 students, thus heading the list of science schools, for the next two subjects in popularity; Elementary Mathematics and Electricity, only number 537 and 485 classes, with 10,502 and 12,515 students respectively.

Dr. Hooker, P.R.S., the learned director of the Royal Gardens, Kew, in arranging the science lessons given during the winter to the young gardeners training in that establishment has, for the past two years, caused a course of lectures on Meteorology to be delivered in addition to the lectures on Botany, Chemistry, &c., and examinations have been held and certificates awarded for proficiency in this science equally with the others.

The movement to spread the knowledge of the principles of meteorology must be a strictly educational one, for experience proves that it is useless to attempt to popularise it by means of lectures to institutions, &c.; for although offered gratis to committees and managers, these are as a rule very reluctant to accept them, as from the absence of brilliant experiments or optical illustrations, they fail to attract large audiences.

The steps taken by the British Meteorological Society during their last and previous sessions, which have resulted in the addition to its ranks of so many officers of health and civil engineers, show that interest is not wanting in the science; and it is only to be regretted that "Spes" has brought forward his proposal so late in the season, that no opportunity can occur for bringing it before the society before their next winter session.

The want of text books on the science now felt would soon disappear, as publishers would at once bring out works on the subject, were a demand for them to arise.

Richmond G. M. WHIPPLE

The Axolotl

WHEN, in 1873, Mr. Mivart published in your pages, in his papers on "The Common Frog," an account of the Mexican Axolotl, I arrived theoretically at conclusions which are, I think, identical with those reached by Weissmann, whose researches, recorded in the *Zeitschrift fur Zoologie*, you published in abstract on the 8th inst. Mr. Mivart says: "Its mature condition was considered to be established by the discovery that it possesses perfect powers of reproducing its kind;" thus seeming to admit that its metamorphosis from the Siredon to the Amblystoma form proves it to have been really a fertile, persistent, larval form. He then used this metamorphosis of a larval into a mature form as a fact in favour of his hypothesis of sudden development; as if the Axolotl and Amblystoma were actually of distinct genera, and not merely the subjects of a mistake arising from partial knowledge, analogous to those by which the larval Nauplius and Zoea were constituted into genera. Sir John Lubbock's remarks on Chironomus ("Origin and Metamorphosis of Insects," p. 76) are relevant. He says: "It seems to me possible, if not probable, that some larvæ which do not now breed, may, in the course of ages, acquire the power of doing so." Persistent larval forms would seem to have originated from adaptational causes, which, Sir John Lubbock remarks, may act through natural selection; and the power of reproduction to have been in time acquired. Any subsequent cases of perfect development from a previously persistent larval form, such as the metamorphosis in question, would seem, as indicated by the absence of sexual power in the resultant Ambly-

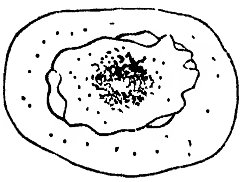
stoma forms, to be analogous to cases of degeneration, or return to an abandoned course of development, rather than to the commencement of a new stage of progress. The adaptational advantages, which caused the larval form to become persistent, ceasing to operate, the Amblystoma form may very possibly, in time, reobtain its reproductive powers and its position as the normally perfect animal of which the Siredon is the larva.

June 28 G. S. BOULGER

Remarks upon a Hailstorm which passed over Belgaum on April 21, 1876

ABOUT 1.30 P.M., after some light rain, large hail-stones commenced falling one here and there, and gradually thickening for ten minutes, were followed up by a sharp shower of rain.

The first stones which fell were of a compressed oval shape, with sides slightly rounded or bulging, about 1 inch in length and ¾ inch in breadth, the centre being about ½ inch thick. The centre or nucleus of the stone was about the size of a large pea, and appeared to consist of a mass of infinitesimally minute air-bubbles. Surrounding this nucleus were two collateral tracings—not rings, for they were far from being round—unlike in form, the one occasionally bulging beyond the other :—



Towards the end of the storm the hail-stones decreased in size and assumed a rounded shape, about ¼ inch in diameter, with the same internal conformation, but proportionately small compared with the size of the stones. G. A. NEWMAN

Williams' (?) Thermometer

As the Physical Loan Collection at South Kensington includes a new (?) thermometer by Mr. John Williams—I presume the son of the late Secretary of the Astronomical Society—I hereby beg to vindicate my priority therein, as printed in the London *Philosophical Magazine* for January 1850, vol. xxxvi. My communication is dated Dec. 6, 1849, wherein I proposed making the common − 40° F. or C. to be the zero, and the boiling-point of water 1000; being 252° F. or 140° C. interval. Also putting zero at − 38° F. to have 250° F. for the extreme difference. This would generally avoid negat. deg. (and even the decimal pointing), merc. freez. − 39 = + 4 or − 4 according to the scale 252 or 250 :—

F. 0 − 158·7	152	F. 150 = 754·0	752
32* = 285·7	280	174 = 849·2	848
39 313·5	308	212* = 1000·0	1000
357·1	352	655 = 2758·0	2772
84 = 492·1	488	672 = 2825·4	2840
98 = 547·6	544		

In a tract on the Limits of the Atmosphere, printed in 1840, I showed that the absolute *zero* of cold is unattainable. Pour any fluid substance in a cylinder, and mark the dilatation points for 32° and 212° F., it is obvious that by carrying the scale downwards to the bottom of the cylinder, that the fluid cannot condense to the very bottom of the vessel, else its density would be infinite. At or before this *lowest* degree of the scale the said fluid will therefore remain stationary or begin to expand upwards, as water does at 32°. I enclose copies printed at the time of my said papers. S. M. DRACH

June 26

The Cuckoo

THERE is a saying in Somersetshire :—

"The Cuckoo sings in April,
The Cuckoo sings in May;
The Cuckoo sings the day before
But not on Midsummer-day."

This year, the cuckoo sang cheerily on the 24th, and is still singing on the 28th with undiminished vigour. H. M. ADAIR

Taunton

Geology of Zermatt

BEING about to spend some time in the Zermatt district, I should be much obliged if any of your readers could give me through your pages (as the information would doubtless be serviceable to others) the titles of such works on the geology and mineralogy of that portion of the Alps as they can recommend from their own use of them. VIATOR

OUR ASTRONOMICAL COLUMN

THE TOTAL SOLAR ECLIPSE OF 1878, JULY 29.—On March 26 of the present year an *annular* eclipse passed over British Columbia, the sun being high in the heavens and near the meridian when the annulus was formed. On July 29, 1878, the still more interesting phenomenon, a *total* solar eclipse, will be visible in the same district, the track of the central line passing thence over the western states of America to the Gulf of Mexico. Our American *confrères* will no doubt give a good account of it.

The duration of totality attains a maximum in British Columbia, and the present remarks will be confined to the passage of the total eclipse over this country. Employing the *Nautical Almanac* elements, which as regards the moon's place are in very close agreement with those of the American ephemeris founded on the tables of Prof. Peirce, and making a direct calculation for longitude 123° 30′ W., latitude 53° 30′ N., we find the following particulars :—

	h. m. s.		
Totality begins July 29, at	1 32 24 local M.T. at	61 from N.Pt.	towards W.
,, ends ,, ,,	1 35 36 ,, ,,	118 ,,	,, E.

The duration is therefore 3m. 12s. The sun's altitude at the middle of the eclipse is 52°.

A similar calculation gives for the commencement of the partial eclipse 0h. 19m. 47s. local M.T. at 62° from the sun's north point towards the west, altitude 56°.

For any other point not far from the above-assumed position the times of beginning and ending of totality may be deduced from the following formulæ :—

$$\cos w = 51{\cdot}5275 - [1{\cdot}84632] \sin. l + [1{\cdot}67405] \cos. l, \cos (L + 203° 44'{\cdot}5)$$
$$t - 9\text{h}\ 59\text{m}\ 4{\cdot}6\text{s}. \mp [1{\cdot}98370] \sin w \quad [3{\cdot}56410] \sin l$$
$$- [3{\cdot}86142] \cos l, \cos (L + 245° 6'{\cdot}7).$$

The beginning of the partial eclipse will be given by

$$\text{Cos. } w = 0{\cdot}98476 - [0{\cdot}19431] \sin l + [0{\cdot}00582] \cos l, \cos. (L + 184° 34'$$
$$t - 10\text{h}.\ 19\text{m}\ 43\text{s} - [3{\cdot}65657] \sin. w - [3{\cdot}55998] \sin. l$$
$$- [3{\cdot}88264] \cos l, \cos (L + 227° 19'{\cdot}4).$$

In the above formulæ L expresses the west longitude from Greenwich taken *negatively*, l the geocentric latitude, and the quantities within the square brackets are logarithms. Upper sign for beginning of totality, lower sign for ending.

The following figures should define pretty accurately the limits of the belt of totality in British Columbia :—

W. longitude	Geographical Latitude of N. Limit.	Central Line.	S. Limit.
° ′	° ′	° ′	° ′
126 30	56 22·1	55 11·0	54 1·4
123 30	54 42·6	53 30·7	52 20·5
122 0	53 50·5	52 38·4	51 27·9
120 30	52 56·9	51 44·6	50 33·9
117 30	51 5·3	49 52·5	48 41·4

Fort Fraser, it will be seen, is very nearly on the line of central eclipse.

At a point, longitude 121° 37′ W., latitude 52° 27′, just south of Lake Quesnelle, the central lines of the annular eclipse of March, 1876, and the total eclipse of July, 1878, intersect.

At New Westminster, the capital of British Columbia, the eclipse is partial only, commencing at 0h. 30m. and ending at 2h. 59m. local mean times, magnitude 0·95.

BESSEL'S "ABHANDLUNGEN."—The second volume of the reprint of Bessel's astronomical and other memoirs, under the editorship of Dr. Engelmann, of Leipsic, has appeared. The contents relate to the theory of instruments, including the treatises of the great Königsberg

astronomer on the heliometer, which in his hands acquired so universal a reputation; to sidereal astronomy, with the memoirs relating to the parallax of 61 Cygni, the measures of the principal members of the Pleiades, to which Dr. Engelmann has added a chart of the group containing stars visible in a telescope of 10·11 cm. aperture, or to "about 10·11 magnitude," the stars not found in Argelander's *Durchmusterung* having a distinguishing mark. Several mathematical essays follow.

MIRA CETI.—Reference is often made in treatises on astronomy to the unusual degree of brilliancy attained by this variable star at the maximum of 1779. From th observations of Bode, Herschel, and Wargentin, we have the following particulars of the augmentation and diminution of brightness in that year.

Aug. 22.—Invisible in an ordinary 2-feet telescope.

Sept. 8.—Seen with the same instrument but very faint.

Sept. 18.—Immediately visible to the naked eye according to Herschel. Bode estimated it 4m.

Oct. 5 and 6.—Already much brighter than Menkar (α Ceti).

Oct. 15-19.—Equal to α Arietis on 15th, and still brighter on the 19th; the light reddish.

Oct. 30.—According to Wargentin, it was equal to Aldebaran and of the same colour, or even of the redness of Mars which was observable the same night. In a 10-feet achromatic Mira shot out vivid red rays. Herschel considered it midway in brightness between α Arietis and Aldebaran.

Nov. 2. There was even an increase, in the judgment of Herschel.

Nov. 11.—Visible as early as Aldebaran and Mars.

Nov. 20.—As bright as, but not brighter than stars of the second magnitude, according to Herschel, but on the 25th much brighter than Menkar, though less than Aldebaran, according to Wargentin.

Dec. 4.—Only equal to α Arietis.

Dec. 7 and 10.—So much diminished since Nov. 25, that it was now hardly equal to Menkar, and its colour was now whiter.

Dec. 25.—Before the moon rose, equal to γ Ceti, or of the third magnitude.

Dec. 29.—Only a little brighter than the fourth magnitude; not equal to γ or δ Ceti.

Argelander gives for the date of maximum 1779, Nov. 6.

THE TASMANIANS

THE *historical* period of this singular race of mankind has lasted no longer than a century, for up to one hundred years ago they had unimpeded sway in the island of Van Diemen. Once invaded by Europeans, they had inevitably to succumb, and they gradually but speedily dwindled away, the last of them having died about two years ago, so that now they are completely extinct.

The island when discovered by Tasman contained about 7,000 inhabitants. In the year 1803 it was annexed by Britain for a penal settlement. Hatred, amounting to display of violence, broke out between the aborigines and the criminal occupiers of the soil. The scattered remnants of the native tribes were subsequently gathered together, and provided for by the Government at various retreats, until the last of the race in course of time passed away. Dr. Barnard Davis, F.R.S., the well-known ethnologist, in a recent paper,[1] endeavours to prove by the comparison of a skeleton, and some skulls of an Australian and a Tasmanian, that these two people belonged to two distinct races of man, having been previously erroneously confounded together.

[1] "On the Osteology and Peculiarities of the Tasmanians, a Race of Man Recently become Extinct." Reprint 4to from the "Natuurkundige Verhandelingen der Hollandsche Maatschappij der Wetenschappen." 3rd Verz. Deel II, No. 4. Illustrated by four splendid lithographic plates.

Almost the only relics which the Tasmanains have left behind them are their bones. Fortunately before the entire extinction of the race, men of science had begun to see the importance of the study of craniology, so that a few skulls, but still only a few, have been collected and preserved. One chief reason of the scarcity of crania is the manner of the disposal of the dead—by fire. These were often placed in a hollow tree, surrounded by spears, so that on the occurrence of any bush fire the bones even were certain to be consumed. Two out of the twelve skulls in Dr. Davis' collection have been rescued from fire. Up to the last three years there was not a single Tasmanian skeleton in any European collection. At the present time there are four in England - two, one a male and the other a female, being in the Museum of the Royal College of Surgeons. Two skeletons, also of opposite sexes, are in the Museum of the Royal Society of Tasmania, Hobart Town.

The chief works of art, of which, unfortunately, but few are preserved, consist of beautiful necklaces made by stringing the iridescent shells of *Purpura elenchus* upon thin sinews, also of very rude implements, chippings of a dark-coloured chert, exactly like that used by the Kanakas of the Sandwich Islands, and, lastly, fishing nets. The natives on the south and west coasts make a kind of "catamaran" from rushes. The spears, about ten feet long, are made of the heavy, hard wood of the "tea tree" pointed and hardened in the fire, and straightened by being passed from end to end between the teeth.

For long the Tasmanians and Australians were confounded together, and Europeans who visited the country did not improve matters by calling both races, without distinction, "black," though the colour of their skin was removed from a negroid blackness, being of a "dull dark" colour in the Tasmanian, and "chocolate, coffee-coloured, or nutmeg-coloured" in the Australian.[1] There was, moreover, a striking difference between the two people, the Tasmanian being stout and broad-shouldered, while there was such a degree of lankness in the Australian as to cause the former to appear stout. Prof. Huxley, who visited both countries, says of the former people that they "are totally different from the Australians."

The Tasmanians were rather short, being below the average of Europeans in stature. The mean height of twenty three men was found to be 5 ft. $3\frac{1}{4}$ in., or 1,618 mm.; that of twenty-nine women was only 4 ft. $11\frac{1}{4}$ in., or 1,503 mm. There are, however, instances, as in other races, of tall stature among the Tasmanians, for several have been found to be 6 ft. in height by measurement. The Australians are a taller people. Out of thirteen Shark's Bay natives who were measured twelve were 5 ft. 10 in in height, but "there seems," observes Mr. Oldfield, "as much variation among these savages as there is among civilised nations, the mean height being no greater than it is in England." The Tasmanians differed strikingly from the Australians in being robuster; and that this is no superficial character, but one of race, can be proved by reference to their bones. A question, now unfortunately too late to solve, is—What was the amount of difference between the different tribes of Tasmania? For it is known that there were tribes in the island differing to the extent of the possession of dialects mutually unintelligible. With regard to the Australians, some ethnologists maintain that they have physical characters so distinct as to admit of being divided into a woolly-haired and a flowing-haired race.

There is, moreover, a striking difference in the structure of the hair in the two races respectively; that of the Australians growing in flowing ringlets, while the hair of the Tasmanian, being excentrically elliptical on section, has a tendency to twist, and thus comes to grow in small

[1] It is to be hoped that in future, in order to avoid such vagueness of terminology, travellers will adopt M. Broca's useful colour-types. *Vide* the British Association's "Anthropological Notes and Queries."

corkscrew locks. This peculiarity allowed them to load their hair with red ochre, so that it hung down in separate ringlets. In colour it is of a very dark brown, popularly called black, approaching in tint to No. 41 [1] of Prof. Broca's "Colour Types." It was difficult to investigate the hair of the women, as, from an idea that it added to their charms, they shaved their heads either with a sharp stone or with broken bottles, on the advent of civilisation! The women among the Mincopies of the Andaman Islands have the same custom. It is a curious coincidence also that the latter race, as did the Tasmanians, were in the habit of carrying fragments of the bones of their relations, as a mark of affection, suspended necklace-wise round their necks. The peculiar growth of hair in spiral tufts is *natural* to these races, which have peculiar crisp excentrically elliptical hair, and is no work of art, being of spontaneous growth, contrary to the assertions of those whose ideas of race are founded on missionary models. The hair on all the other parts of the body, of which there was no deficiency, was of the same character, there being even on the borders of the whiskers little pellets of hair on the cheeks, "like pepper-corns." The nose of the Tasmanian was not elevated, but very broad across the alæ. The upper lip was long, and the mouth wide, but of a pleasant, calm expression. In the strength of the jaws, moreover, the size of the teeth, and the large area of the grinding surface of the molars, the Tasmanians agree with the Australians, and contrast strikingly with European races.

There is a peculiarity in the physiognomy of the Tasmanians which is difficult to describe to others, but which is obvious to those, who, like Dr. Davis, have long studied their crania. It consists in "a particular roundness, or spherical form, which manifests itself in all the features." Dr. Paul Topinard, too, states ("Etude sur les Tasmaniens," Mém. de la Soc. d'Anthrop. de Paris, iii. 309) that there are certain marks in the cranium which would "enable him to recognise it anywhere."

The thickness and density of the bones of the skull, even in women, is very striking, and "constitutes a decided peculiarity of the race." The frontal and parietal bones, for instance, of a small woman's skull, from which the calvarium had been sawn off, was 0·4 inch, or 6 millimetres, in thickness. The orbits in the Tasmanian skull are, according to Dr. Topinard, small. He says, moreover, that the skull has a sinister expression, while, on the other hand, Dr. Davis regards the countenance of the Tasmanian as a "benevolent, if not mild," one.

With regard to prognathism, both in superior alveolar and in inferior alveolar, or *mental* prognathism, the Australian cranium much exceeds that of the Tasmanian.[2] This is well seen in Dr. Davis's plates (Tab. II. III.).

Touching cranial capacities, Dr. Topinard concludes that "the anterior lobes of the brain have *nearly the same* relative development in the two series of skulls, *i.e.*, the Tasmanians and others" [that is, Parisian and Breton skulls taken for comparison]. "The anterior part of the posterior cerebral lobes is a *little less* developed in the Tasmanians. The posterior part is *much less* developed. The cerebellum is more voluminous in the Tasmanians, by a quantity approximately equal to the loss which the posterior cerebral lobes undergo."

On examining the skeleton of a Tasmanian it will be observed that the bones have the usual robustness seen in European skeletons, differing thus quite from those of the Australian, which are slender. In two skeletons each belonging to one of these races, the last rib was in both three inches long, while in those of an Australian woman described by Prof. Owen this rib was but little more than one inch in length. The ilia are decidedly more everted in the Tasmanian than in the Australian. The patellæ are also larger in the former. There is no olecranon foramen in the humerus of either skeleton. The tibiæ are, moreover, straight in both, and not of sabre form.

In twenty-four Australian skulls of both sexes, there was a mean weight of brain of 41·38 ounces, or a mean internal capacity of 81·1 cubic inches, while in eleven Tasmanian skulls of both sexes the mean cerebral weight was 42·25 ounces, or a corresponding cranial capacity of 82·8 cubic inches. From this it may be deduced that the Tasmanian excels the Australian in having a brain ·87 oz., or twenty-four grammes heavier, or an internal capacity of skull superior to the extent of 1·7 cubic inch. This squares with Dr. Topinard's observations.

This being the case, we should suppose that the inventive powers of the Tasmanians would exceed those of the Australians; but this, possibly owing to some extra stimulus to the invention of the latter race, is not the case. It seems, indeed, probable that it was the abundance of food in Tasmania which was the cause of the non-invention of two of the implements so necessary to the Australian when engaged in the chase, to wit, the "boomerang" and the "wommera," or throwing stick, by which spurs were hurled, both of which are indigenous to Australia, not being known elsewhere. The Tasmanian had, indeed, the "waddy," a short stick of hard wood, which they threw with a rotatory motion so as to kill a bird on a tree, but this was a far less elegant weapon than its Australian representative, the boomerang. As evidence that the invention of implements is not commensurate, wholly and simply, with cerebral development, we must bear in mind that the bow and arrow, so useful to the Asiatics, Pacific Islanders, and American Indians, was never discovered either by the Tasmanian or Australian.

A surprising deficiency among the Australian and Tasmanian tribes is a total absence of pottery, and this among many races that had no substitute in the pericarp of fruits. This is a hard fact for those who would fain believe in the derivation of Australian and Tasmanian from other races. In some parts of Australia where long drought has been suffered the natives have actually used the dried calvarium of a deceased person, cementing the sutures with a vegetable gum, upon which they stick the shell of an oyster to protect the resin from being rubbed off. The Tasmanians were further quite unacquainted with the shield. Nothing is so demonstrative of the complete isolation of the Tasmanians as the fact that, though separated from Australia by a strait but little more than 300 miles wide, there had been no intercommunication from either side between the two countries until the advent of Europeans. This fact tells strongly against those who believe in the almost universal spontaneous diffusion of races. The Tasmanians further had no native dogs, nor was the practice of circumcision known among them, facts tending further to prove the isolation of the two races. Neither this race, moreover, nor the Australians of the south, were in possession of boats, so that even the intermediate islands in the straits were quite uninhabited. There is reason, however, to believe that, like the Australians, some tribes of the Tasmanians were accustomed to punch out the front teeth. This rests only on osteological evidence, as no account has ever been given of the prevalence of the custom among this race.

Finally, "all that can be said with truth is that the Tasmanians are not Australians, they are not Papuans, and they are not Polynesians. Although they may present resemblances to some of these, they differ from them substantially and essentially." From this it may be concluded that the Tasmanians were one of the most isolated races of mankind which ever existed. They have been one of the earliest races to perish totally by coming in contact with Europeans, and "their record now belongs wholly to the past." J. C. G.

[1] The darkest.

[2] In a skull, however, of a male Tasmanian about thirty years o age, belonging to Dr. Davis, the prognathism, both mental and supra-alveolar, is greater than in that of an Australian youth about twenty years old.

THE KINEMATICS OF MACHINERY[1]

THE study of pure mechanism, a branch of kinematics, in general consists of the solution of the following problems:—Given the mode of connection of two or more points or bodies with each other, required their comparative motion, and conversely given their comparative motion to find their proper connection. Now the comparative motion of two points is determined, as laid down by Willis, when (1) the velocity ratio or the proportion which their velocities bear to each other, and (2) their directional relations, are known; the latter requiring for its complete determination (*a*) the angle between the directions compared, (*b*) the angle which the plane containing the two directions makes with a plane fixed in space, and (*c*) the angle the intersection of the two planes makes with a fixed line on the latter plane. In "Kinematics of Machinery," the English translation by Prof. A. B. W. Kennedy of Prof. Reuleaux's "Theoretische Kinematik,"[1] the study is confined within narrower limits, causing the translator not a little difficulty, as he expresses in his preface, to translate the word kinematic, carrying as it does a more extended signification here than on the Continent. Starting with the condition that the change of position is definite at each instant, and determined by the form and connection of the fixed and moving parts, Prof. Reuleaux proceeds to investigate the directional relations of the motion and the arrangements of the parts by which the motion is best brought about without any reference to the idea of velocity.

On turning to the Appendix, pp. 585–589, we find a most interesting historical collection of the definitions of

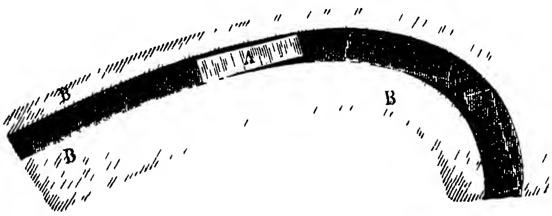


FIG. 1

a machine, one of which definitions we remark includes equally an adhesive fly-paper and the red-hot poker of the clown; that given by Reuleaux, p. 35, is more concise and certainly nearer the point than most of these. "A machine is a combination of resistant bodies so arranged that by their means the mechanical forces of nature can be compelled to do work accompanied by certain determinate motions."

Thus the prevention, by the resistance of the different parts, of all motion other than that desired, as well as the conversion into useful work of as much of the energy expended as its *efficiency* permits, is the function of the machine. "Those parts of a machine transmitting the forces by which the moving points are caused to limit their motions in the definite and required manner, must be bodies of suitable resistant capacity; the moving parts themselves must belong also to similar bodies." But the determination of the suitable form and sectional area of the resistant parts, though indispensable in the construction of the machine, belongs to another part of the study of machine design, and cannot be included in the kinematic discussion.

We now come to the conception of a pair of elements. In order that a body B (Fig. 1) may prevent all other motion in the body A than that desired, A being assumed to move in a plane, B must be given a form such that it always remains in contact with A in all its required positions; when that has been done no other motion can be given to A with respect to B. This geometrical form of B is called the envelope of A, and it is plain that the motion of B with respect to A, considered fixed, is the same as that of A with respect to B, and that no other motion of B with respect to A is possible; that is, A is also the envelope of B. The relation is thus seen to be reciprocal. A combination of this sort is called a pair of elements, and a machine consists solely of such elements, corresponding reciprocally in pairs. "The shaft and the bearing, the screw and the nut are examples of such pairs of elements. We see here that the kinematic elements of a machine are not employed singly, but always in pairs, or, in other words, that the machine cannot so well be said to consist of elements as of pairs of elements. If a kinematic pair of elements be given, a definite motion can be obtained by means of them if one be held fast or fixed in position. The other element is free to be moved, but only in the one particular way allowed by the constitution of the pair."

In order to combine two pairs of elements *a b* and *c d*, we must unite each element of one pair with one of the elements of the other pair. If this is effected as in Fig. 2, no new motion is obtained, as also when they are in the same straight line; but if *a* and *d* are united in such a manner as not to be parallel or in one straight line, the motion is entirely altered, and any points between *b* and *c* will describe a curve. In either of these two cases having united *a* to *d* and *b* to *c*, we have only two resistant bodies each limiting and determining the relative motion

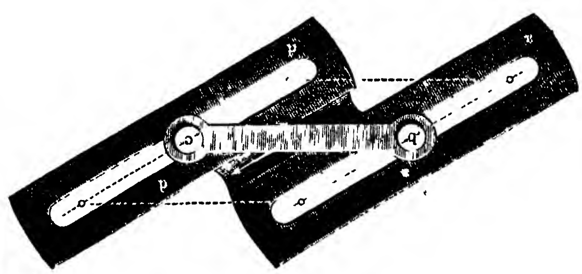

FIG. 2

of the other; thus the two pairs of elements are reduced to one pair, in one case with the same, in the other with a different motion.

"Accordingly, the reciprocal combination of the elements of two pairs gives us again a pair of elements which may differ from either of the single pairs of which it is composed." Again, a combination of three, four, or more pairs of elements may be made, each element of each pair being combined with one element of another pair, thus forming a linkage returning upon itself, or a so-called closed kinematic chain. Fig. 3 shows this combination. As a good example of this, the beam, connecting rod and crank of a beam-engine may be taken; *a* and *b* are the Plummer blocks of the crank shaft and main centre rigidly connected together by the bar *a h*, which represents in the engine the rigid connection of these two by the frame, supports, and bed; *b* the crank-shaft rigidly connected by the crank with the crank-pin *c*; *d e* the connecting rod rigidly connecting the crank pin *c* with the gudgeon *f*, and lastly, the beam *e h* rigidly connecting the gudgeon *f* with the main centre *g*. In this closed chain of four pairs of elements the only motions of each part with respect to *a h* regarded as fixed are readily seen. Thus we are led on to the result that "the mechanism is a closed kinematic chain; the kinematic chain is compound or simple, and consists of kinematic pairs of elements; these carry the envelopes required for the motion which the bodies in contact must have, and by these all motions

[1] "The Kinematics of Machinery: Outlines of a Theory of Machines." By F. Reuleaux, Director of and Professor in the Königlichen Gewerbe-Akademie in Berlin, Member of the Königl. technischen Deputation für Gewerbe. Translated and edited by Alex. B. W. Kennedy, C.E., Professor of Civil and Mechanical Engineering in University College, London. (London: Macmillan and Co., 1876.)

other than those desired in the mechanism are prevented." When one of the mechanical forces of nature, such as that of falling water, moving air, or expanding steam, is applied to one of the movable links in such a manner as to cause it to change its position, mechanical work is performed accompanied by certain determinate motions, and the whole is called a machine. The relative motion of two bodies in a plane is next considered, and the conceptions of the instantaneous centre and of centroids

FIG 3

introduced. At each instant of the motion in a plane of one body with respect to another considered as fixed, the motion can be accurately represented by a rotation in the plane about a fixed point, which, however, in each succeeding instant may occupy a different position; this point is called the instantaneous centre, and the positions it occupies in successive instants trace the centroid. Space will not permit us to show the formation of the reciprocal centroid, or how the motion of the moving body can be represented at each instant by the rolling on one another of the centroids, and the motion of any points connected rigidly with the moving body determined when the centroids are known, but the example given as illustrating the determination of relative motion from the known centroids will speak for itself. The centroids given are a circle and straight line which roll on each other. All points rigidly connected with the circle

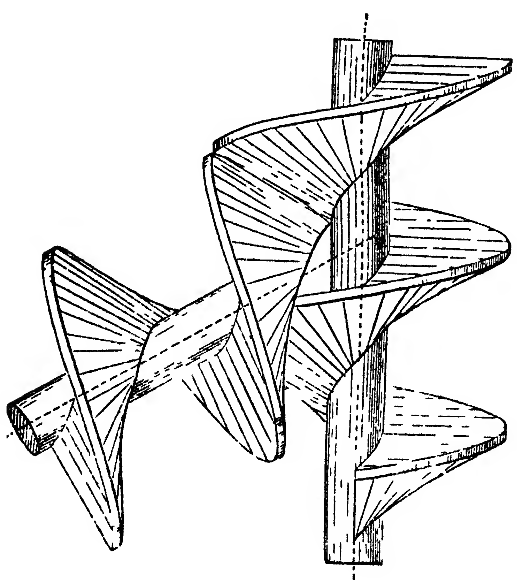

FIG 4

describe trochoids, the line being regarded as fixed; all points rigidly connected with the straight line describe involutes, the circle being considered fixed, and all these paths are determinate, and can be constructed if the position of the moving point with respect to the moving element, circle or line, and the centroids, the line and circle are given.

From motion in a plane and the determination of centroids, we pass to motion in space. If the position of three points in a rigid body not in the same straight line are known, the position of any other point in it may be determined from them, and if the three points are fixed in space the body is also fixed. Thus, to determine the relative motion of two rigid bodies in space, we have only to consider the motion of two triangles fixed one in each of them; or the motion of one triangle fixed in the moving body with respect to the other reduced to rest. The change of position of the moving triangle may take place in many ways, but it may in every case be effected by its translation parallel to itself in a line joining the old and new positions of one of its angular points, and then by a rotation about an axis through the new position of that angular point. Thus any change of position of a rigid body may be effected by a simple translation and a simple translation about an axis. The simplest case is when the translation takes place along a line parallel to the axis of rotation, when, if the change of position of the moving body be taken indefinitely small, the instantaneous axes of rotation along which sliding simultaneously takes place become indefinitely near each other; the motion is then a simple twist.

"Consider a pair of bodies having conical rolling, in which both cones have a motion of translation in space. The rotation then takes place through the conical rolling, and the sliding through the translation of the pair of bodies." Next "consider the consecutive positions of the axes as forming a pair of ruled surfaces, one for each body, so that the motion is reduced to the rolling of the two ruled surfaces upon each other with a simultaneous endlong sliding upon each other of the generators which are in contact. The surfaces of these solids being the loci of the axes, are called axoids. Thus all relative motions of two bodies may be considered as the twisting or rolling of ruled surfaces or axoids." The ruled surfaces roll on each other without sliding, when all the axes meet in a point as in a pair of cones or a cone and cylinder; also when the point of intersection is at any infinite distance, as in the case of two cylinders with parallel axes. These are, however, only particular and more obvious cases of the general condition of rolling without sliding, viz., that the two ruled surfaces are developable on each other.

APPARATUS FOR REGISTERING ANIMAL MOVEMENTS[1]

THE registering apparatus which have enabled us to carry so far the investigation of the functions in living animals are applicable to the analysis of movements of every kind in health and in disease. It is to this important application that I desire to draw your attention at the present time.

Most of the movements whose various phases we have to estimate must be transmitted to a distance, preserving at the same time all their characteristics. It is by the medium of the air that this transmission is effected, and its principle is as follows:—

Upon the organ (muscle, artery, heart) whose movements are to be investigated an apparatus called the exploring drum is applied. It is a small metal basin closed by a caoutchouc membrane, and communicating by a longer or shorter tube with a similar drum, upon the membrane of which is supported a recording lever. The pen with which the extremity of this lever is provided inscribes the curve of the movement impressed on the membrane of the first drum on a cylinder covered with smoked paper and turning on a horizontal axis.

1. Let us at once apply the process of analysis to the muscular movements of man. For this purpose we may either grasp the muscles of the ball of the thumb between the flattened jaws of the pincers which I show you, or apply to the fleshy substance of any muscle an exploring drum, the knob of which rests upon the muscle. When by means of electricity we cause a contraction or tetanus of the muscle to be studied, the curve of the contraction or that of the tetanus is recorded at a distance upon the revolving cylinder.

This apparatus shows the thickening which a muscle undergoes

[1] Paper read in the Biological Section at the Loan Collection Conferences, by Prof. Marey.

during contraction, and it furnishes results identical to those obtained by investigating the shortening of the muscle during contraction in living animals. We are then quite authorised to interpret in the same way the curves obtained in both cases.

It is needless to insist on the numerous services which the myography of man may render to physiology and medicine. The study of the forms of movement, of the latent period, of muscle, and perhaps even the rate of transmission of impulses along motor nerves, by means of this apparatus may be as easily pursued in healthy or unhealthy men as in animals.

2. Without quitting the investigation of muscular movements, let us examine that of the respiratory movements, and we shall obtain valuable information as to the means by which the important function of respiration is effected. We apply to the chest this apparatus formed of an elastic plate and furnished with two lever arms, to the extremity of which is attached a band which surrounds the thorax. Each dilatation of the chest causes the spring to bend, and it resumes its position during respiration. This double movement is accompanied by a rising and falling of the membrane of the drum which forms part of the apparatus, and which therefore becomes a regular bellows, causing the elevation and depression of the inscribing lever placed beside the cylinder.

The respiratory curves thus obtained present certain normal characteristics susceptible of being greatly modified when any obstruction interferes with the respiratory functions either by impeding the entrance or the exit of the air, or even by opposing its passage in both directions. In all these cases the curves have a special physiognomy, and their simple inspection enables us to recognise the seat of the obstacle to respiration. Clinical research will yet discover here many points for investigation.

3. But above all there are the phenomena of circulation, which have been minutely investigated both in man and animals. The apparatus by means of which we can completely analyse the movement of the heart, the arterial pulse, &c., have already rendered great service; we are, however, right in expecting yet more from it, by making use of it in clinical investigations.

Of various cardiographs, that on which I wish to dwell differs little from the explorer of which I have already spoken. The knob with which it is provided is applied to the region of the apex of the heart, and each beat of the organ is transmitted to the recording lever. There is seen in this pulsation of the heart the same elements which the physiological cardiograph has revealed in the higher animals. This beating of the heart is then a complex act, and the numerous details which have been discovered by graphic analysis have each a considerable importance from the point of view of functional investigation. One part of the tracing shows us how the ventricle is emptied into the artery; another enables us to appreciate the play of the auricle, the beating of the sigmoid valves, &c. You will easily see that the precise diagnosis of affections of the heart, already carried so far, thanks to auscultation, will be greatly improved by the application to man of the cardiograph applied to the study of the pulsation of the heart.

The arterial pulse cannot be separated from the pulsation of the heart in the study of the phenomena of circulation in man. Already numerous researches have been undertaken by means of the direct sphygmograph; but much more may be expected from the use of the air sphygmograph (*sphygmographe à transmission*).

I place this apparatus upon my wrist, and the artery raising a spring connected with the membrane of the exploring drum, transmits its movement to a distance by means of the tube filled with air, which enables this sphygmograph to communicate with the drum to which the recording lever is attached. By recording simultaneously the traces of the pulse and those of the heart much information may be obtained and many errors avoided.

4. I shall present to you, in conclusion, a new method of investigating the peripheral circulation. This method is based on the principle that the variation of the calibre of the blood-vessels in any part of the body is faithfully indicated by the variations of the volume of that part. Without dwelling on the history of these investigations, I may tell you that they originated many years ago, Dr. Piégu, of Paris, having pointed out in 1846 the alternate expansion and contraction of the tissues in connection with the dilatation and contraction of the blood-vessels. Since that time Chelius and Fick in Germany, Mosso in Italy, Franck at Paris, have carried on and extended these researches.

The recording of the movements of a column of water inclosed in a tube communicating with a receiver filled with water and into which the hand and forearm is plunged, was first effected by Fick by means of a float armed with a pen. Ch. Buisson hit on the happy idea of transmitting to a distance, by means of tubes filled with air, the oscillation of the column of water, and it is with his apparatus that M. Franck, in my laboratory, has executed a series of researches. You see the apparatus in action. The hand is plunged into this jar filled with water and hermetically closed. A vertical tube, furnished with a bulb to avoid the effects of the speed acquired by the liquid, serves to transmit to a recording lever the oscillation of the column of water. You will remark that these oscillations are rhythmical with the heart, and if we record them by the side of the cardiac pulse registered by the transmitting sphygmograph, we can establish the identity of the variations in size or, as we may term them, the pulsations of the hand and of the pulsations of a single artery. With this apparatus we may perform numerous experiments on the mechanical effects of compression of the arteries or veins, the action of the vaso-motor system of nerves, direct or reflex, &c.

I shall not explain to you by the side of this method of investigation, that which we owe to Mosso, of Turin His plethysmograph, which ought soon to be presented to you, permits the estimation of changes of volume of the hand, and, assuredly, the combination of these two processes ought to lead to important results in the investigation of the phenomena of peripheral circulation.

I have sought to submit to you some of the points more immediately applicable to man, without dwelling on the investigation of the movements among animals. But these two orders of researches complement each other. We may say that most of the data furnished by experimentation on animals are now susceptible of rigorous verification on man, healthy or unhealthy. This verification we owe to investigation by means of precise apparatus and to the recording of the smallest movements, thanks to the registering instruments, the principal specimens of which are shown in this Collection.

DREDGINGS OF THE "CHALLENGER"

PROF. WYVILLE THOMSON had not set foot long in Old England before presenting in person a preliminary quota of his results to the learned bodies. Two papers read by him at the Linnean Society on June 1, embodied observations on Echinodermata, a group to which, as is well known, he previously had paid much attention. One of the communications described some new living Crinoids belonging to the Apiocrinidæ. Of deep-sea forms the stalked crinoids are extremely rare, and have a special interest on account of their palæontological relations; it was therefore with satisfaction that near St. Paul's rocks at 1,850 fathoms, the trawl brought up, among other things, an entire specimen of a new crinoid, *Bathycrinus Aldrichianus*, and fragments of another, *Hyocrinus bethellianus*. At other stations and on different occasions, were obtained another species of *Bathycrinus* (*B. gracilis*) and an undetermined beautiful little species of *Hyocrinus*, besides examples of the *Rhizocrinus lofotensis* of Sars; all of these being referable to the Apiocrinidæ. In pointing out their structural peculiarities and alluding to *Bathycrinus*, he mentioned that the stem barely enlarges at its junction with the cup, the ring formed by the basals is very small, and the first radials are free from the basals and often free from one another, while the oral plates are absent. This genus appears to possess an assemblage of characters in some respects intermediate between *Rhizocrinus* and the pentacrinoid stage of *Antedon*. *Hyocrinus bethellianus* has much the appearance, and in some prominent particulars it seems to have very much the structure of the palæozoic genus *Platycrinus* or its sub-genus *Dichocrinus*. The stem is much more rigid than that of *Bathycrinus*; the cup consists of two tiers of plates only, the lower is to be regarded as a ring of basals, and the upper consists of fine spade-shaped radials. There are five arms which are pinnulated. The proximal pinnules are very long, running on nearly to the end of the arm, and the succeeding pinnules are gradually shorter, all of them, however, running out to the end of the arm. Distally the ends of the five arms, and the ends of all the pinnules meet nearly on a level. This arrangement is unknown in recent crinoids, although we have something close to it in species of the fossil genera *Poteriocrinus* and *Cyathocrinus*; with this, however, their resemblances end. *Rhizocrinus* finds its ally in the cretaceous genus *Bourgueticrinus*; *Bathycrinus* and *Hyocrinus* are evidently related to the former, but the characters of the Apiocrinidæ are nevertheless obscure in

the two latter. In his second paper Prof. Wyville Thomson drew attention to peculiarities in the mode of propagation of certain Echinoderms of the Southern Sea. He passed in review examples of the Sea-cucumbers (*Holothuroids*), Sea Urchins (the circular *Cidaroids*, and heart-shaped, *Spatangoids*), Star-fish (*Asteroids*), and the Brittle Stars (*Ophiuroids*). In allusion to their phases of development he stated the majority of these pass from the egg without the intervention of a locomotive pseudembryo. Among other data in support of this view he said, that while in warm and temperate seas "plutei" and "bipinnari" were constantly taken in the surface-net; yet during the southern cruise between the Cape of Good Hope and Australia, only one form of Echinoderm pseudembryo occurred, and which was considered with some little doubt as the larva of *Chirodota* from the presence of dermal, calcareous, wheel-shaped spicules. Furthermore Prof. Wyville Thomson described in detail the almost constant occurrence among the majority of the foregoing groups a curious, receptacular pouch wherein the young are carried until arriving at a certain maturity. This marsupium is situated on the dorsal portion of the body, is composed of a series of plates which meet centrally and permit of the young creeping about and returning to it for shelter. The young derive no nutriment from the parent while contained in the "nursery," other than it may be a mucous secretion.

THE U.S. WEATHER MAPS[1]

IN this fourth contribution to meteorology, Prof. Loomis discusses certain points of a miscellaneous nature which have been either very slightly or not at all examined in his three previous contributions. The movements of areas of high barometer, which are of so great importance in their relations to weather and climate, have been examined with the result that while the average track of areas of low pressure across the United States is nine degrees to the north of east, the track of areas of high barometer advance toward a point several degrees south of east, and with a velocity somewhat less than the former.

As regards the conditions under which the monthly minima of temperature occur, it is shown that these conditions, viz., winds very light, sky clear, and pressure above its mean height, are substantially the same at Jakutsk, Siberia, as at New Haven. Prof. Loomis is of opinion that it is true universally that periods of unusual cold are generally accompanied by a barometer above the mean, and by a descent of air from the upper regions of the atmosphere. These areas of high barometer have a broader significance than is here implied. It is the still, clear, and dry atmosphere accompanying them, *and its relations to terrestrial and solar radiation*, which afford the conditions of extreme temperatures. The monthly minima of the cold months of the year and the maxima of the warm months both frequently occur under the conditions afforded by areas of high pressure. On the other hand, in North-western Europe it is often observed that the minima of temperature during the warm months repeatedly occur within areas of low pressure where very light easterly and northerly winds prevail. In discussions of the relations of temperature and pressure, it is seldom kept steadily in mind that the given temperature is merely the temperature observed within a few feet of the earth's surface, which, as regards areas of high pressure, will nearly always mislead if it be used as a basis from which to estimate the temperature of the higher strata vertical to it; the surface temperature being abnormally low in winter from contact with the cooled surface, and in summer abnormally high from contact with the heated surface of the earth.

The examination of storm paths in America, the Atlantic, and Europe is important from the bearing of the subjects on climatology and weather-forecasting. Some interesting results of such an examination are given by Prof. Loomis in the average paths marked on the chart accompanying the paper. The results, however, are not calculated to be practically useful until the average paths be laid down for each month in the year, owing to the very great differences in these paths as regards different months. Thus, in North-western Europe, during the spring months, when east winds are most prevalent in Great Britain, many storm tracks, or the course of barometric depressions, are more southerly, and during the winter months more northerly than that indicated on the chart. If the track of storm-centres in winter generally took the line of The Channel, our winters would, on the average, be much more severe than they are, owing to the greater frequency of easterly and northerly winds, which would necessarily follow. But open winters are the rule in these islands, and even as far north as Faroe, where, during winter, southerly and westerly winds largely preponderate, thus showing that the central tracks of the majority of our winter storms lie to the north of Faroe. The exact determination of the average monthly tracks and the more marked deviations from them would throw light on several important questions affecting the climatology of the whole of North-western Europe.

Since the average velocity of storms over the United States as deduced by Prof. Loomis from 485 cases, is twenty-six miles per hour, and over the Atlantic, as deduced from 134 cases, is 19·3 miles per hour, and the average velocity of European storms as deduced by Prof. Mohn is 26·7 miles per hour, it follows that storms travel less rapidly over the ocean than over continents. If further inquiry confirms this result, we have here a valuable contribution to the theory of storms which will likely lead to a clearer insight into the causes which regulate their rate of propagation over the earth's surface, accelerating it in some cases, and in others retarding it as is frequently seen off the coast of Newfoundland and in the Bay of Biscay.

[1] Results derived from an examination of the United States Weather Maps and other sources. By Prof. Elias Loomis, Yale College. Fourth Paper. From the *American Journal of Science and Arts*, vol. xi., Jan. 1876.

NATURAL SCIENCE AT CAMBRIDGE

THE Cambridge Natural Science Tripos has just entered upon a new phase of existence. The recent examination is the first in which a division into two parts, elementary and advanced, is carried out, the former being held in June and the latter in December. Candidates who do not satisfy the examiners in the first part are not permitted to compete in the second. The final class-list is to be based on the alphabetical principle, but the first class will consist of two divisions, each arranged alphabetically, and the subject or subjects for which a man is placed in the first class are to be indicated, while a special mark will reward superior proficiency. This system removes some of the worst faults of the competitive system, and is of especial benefit to the more able men. One subject will not be pitted against another as regards marks, an accumulation of cramming in several subjects will not serve an inferior man, and clear testimony will be given that a man has a competent knowledge of a subject, or that he is specially proficient in it. With such arrangements, the value of the examination will largely depend upon the wisdom of individual examiners. It will be obvious that there should be at least two examiners in each subject instead of one. Also the pittance they receive should be transformed into fair remuneration, which will, no doubt, be done as soon as the University has more funds at its disposal.

It was to be expected that a new system, by which no man receives any credit in a subject unless he shows satisfactory knowledge of it, and by which the examination is limited to three days, would produce a large number of failures to attain honours. The number of candidates in June was forty-four, a large increase; of these only thirty-one obtained honours, while ten others received the ordinary degree. On scrutinizing the papers, it appears that there is a difficulty in equally adjusting the questions which probably have affected the result. Two questions in each subject, except human anatomy, are given in every paper; one question only is set in human anatomy, which is introduced for the first time. I will quote some of the questions in geology and in physiology, giving fair samples; and it will be plain that they are not equivalent in difficulty, and that students of moderate ability and reading might gain honours by answering the former much more easily than the latter.

"In which of the three great divisions of stratified rocks do fossils of the genera Ichthyosaurus, Phacops, Calamites, Voluta, Terebratula, Ostrea, and Micraster respectively occur?" "Volcanic rocks have been divided into two classes, acidic and basic. Give the name and mineralogical composition of a common rock of each

class." "To what conditions of deposit do fossils of the following groups of genera respectively point?—1. Unio, Paludina, and Cyrena. 2. Nautilus and Globigerina. Illustrate this by reference, in each case, to a British example."

"Explain what is meant by 'arterial tonus.' State generally what is the origin, course, distribution, and mode of termination of the nervous channels by which the brain and spinal cord influence arterial tonus." "Describe the rhythmical respiratory movements of the glottis in mammalian animals, referring to the mode of action of the most important muscles which are concerned in their production."

I only wish to point out the contrast in difficulty between the above sets of questions, without offering any opinion as to the suitability of either. In zoology and comparative anatomy the following question seems rather unusual for such an examination.—"Briefly describe the internal economy of a beehive, and the mutual relationships of its inmates." Here is a question in geographical distribution:—"In what countries are the following animals found—the orang utan, vampire-bat, tapir, leopard, elk, emu, and python? State what principles of zoogeography are deducible from their distribution." It seems to me that a knowledge of the distribution of all the more important species is far beyond the pass qualification for an honours' examination. In admitting men to such a qualification, tests should rather be applied which every student of a subject ought to be able to respond to; but it is questionable whether we can yet expect every student of zoology and comparative anatomy to "state concisely the doctrine of evolution as employed in biology."

It is not stated in how many subjects a candidate must pass in order to obtain honours; nor are any named as essential. There is a strong feeling that elementary chemistry and physics should be made compulsory on all, and that students should be allowed to present themselves in these subjects at an earlier period of their course.

G. T. BETTANY

NOTES

WE are glad to learn that upwards of 1,000*l*. has been subscribed towards the Chemical Society Research Fund, so that the Council are now in a position to accept Dr Longstaff's generous offer of 1,000*l*. to form a permanent fund. We only hope that the fund may still be largely increased.

THE Albert Medal of the Society of Arts for "distinguished merit in promoting Arts, Manufactures, and Commerce," has this year been unanimously awarded to Sir George B. Airy, K.C.B., the Astronomer Royal, for "Eminent Services rendered to Commerce by his Researches in Nautical Astronomy, and in Magnetism, and by his Improvements in the Application of the Mariner's Compass to the Navigation of Iron Ships." A prize of a Gold Medal was awarded to Mr. Hearson for the best "Revolution Indicator," which should accurately inform the officer on deck, and the engineer in charge of the engine, what are the number of revolutions of the paddles or screw per minute without the necessity of counting them. For papers read before the Society medals have been awarded as follows:—To Mr. Clements R. Markham, C.B., for his paper "On the Cultivation of Caoutchouc-yielding Trees," Mr. W. T. Thornton for his paper "On Irrigation Works in India," Mr. E. Hutchinson for his paper "On the Development of Central Africa," Mr. W. Valentin for his paper "On Dextrine-Maltose, and its use in Brewing."

MR. H. N. MOSELEY, M.A., has been elected to an Extraordinary Fellowship at Exeter College, Oxford, tenable for five years under a special ordinance sanctioned by the Visitor. Mr. Moseley, who was educated at Exeter College, proceeded to his B.A. degree in 1868, having obtained a "first class" in natural science in Trinity term of the same year. He was elected in 1869 Radcliffe Travelling Fellow, and has recently been one of the scientific staff of the expedition of H.M.S. *Challenger*.

M. WADDINGTON intends to establish Fellowships in the several French Academies in imitation of the Fellowships of the English Universities. The French Fellowships are to hold good only for a limited period, and will not be subject to the restriction of celibacy. The credits will soon be asked for from the French Assemblies.

IN the University of London D.Sc. Examination Mr. Thomas Carnelley and Mr. Frank Clowes have passed in Inorganic Chemistry, Mr. James Gordon MacGregor in Electricity (treated experimentally), Mr. Edward Bibbins Aveling in Vegetable Physiology, and Prasanna Kumár Ráy in Logic and Moral Philosophy.

ON Thursday last the master and other members of the London Clothworkers' Company visited Leeds, in order to inspect the working of the Textile Industries' department of the Yorkshire College of Science, which was founded and endowed by the munificence of the Company. The visitors expressed their satisfaction with the results of the endowment, and the master, Mr. Wyld, in replying to the toast of the Company, showed that he had an unusually high idea of the duties which devolved on the London Companies as trustees of the large funds which belonged to them. While placing a high value on technical education, moreover, he expressed the opinion that any special education divorced from, or not based on, wide general culture, would be defective and inefficient.

MR. LLOYD, the president of the trustees of the Fisk donation for the construction and fitting up of the San Francisco Observatory, arrived in Paris at the end of June. His first visit was to M. Leverrier, who gave him every assistance in his power to enable him to fulfil the object of his mission. Mr. Lloyd is at liberty to use the observatory grounds for any experiments in connection with his large refractor, which it is intended to construct. M. Leverrier concurred with him in not attempting to construct a lens of more than one metre in diameter. The money at the disposal of Mr. Lloyd is 200,000*l*. The law-suit is at an end, and the donation of a similar sum for the museum is cancelled, but the astronomical donation has been confirmed.

PROF. H. G. SEELEY has been appointed Professor of Geography at the Queen's College for Ladies, Harley Street.

THE Geologists' Association are to make an excursion to the North Wales Border on Monday, July 17, and five following days.

THE forty-second annual meeting of the Statistical Society was held on June 27, at the Society's Rooms, the President, Mr. James Heywood, F.R.S., in the chair. The report read showed that the Society continues to advance steadily in numbers and in public estimation.

WE have before us the commencing number of "The Proceedings of the Linnean Society of New South Wales," which contains papers by Mr. Brazier, C.M.Z.S., on a new species of Australian and Solomon Island shells; by Mr. Ramsay on a new species of *Ptilotis* from the Endeavour River, with some remarks on the natural history of the East Coast Range near Rockingham Bay, and by Mr. Maclean, the President of the Society, on a new species of *Dandrophis* from Cleveland Bay. We are convinced that a work so well commenced has the good wishes of all interested in the diffusion of science.

MR. ALEXANDER AGASSIZ, in his recent trip to Peru, found occasion to conclude that the Pacific, within a comparatively recent time, extended through gaps in the Coast Range, and made an internal sea which stood at a height of not less than 2,900 feet, and probably much above this. This is proved by the fact of the occurrence of coral limestone 2,900 or 3,000 feet

above the sea level, about twenty miles in a straight line from the Pacific. The corals are of modern aspect, although the species are undescribed. The fact that there are extensive saline basins at a height of even 7,000 feet on the coast of Peru would seem to indicate that the submergence was at one time still greater than that suggested. Indeed, eight species of *Allorchestes*, a salt-water genus of amphipod crustaceans found in Lake Titicaca, would seem to indicate that this lake, 12,500 feet above the sea, must have been at one time at the sea-level.

WE have received Part II. of vol. ii. of the *Transactions* of the Norfolk and Norwich Naturalists' Society. The Society, which has just completed its seventh year, has gradually been increasing in numbers, and there are now 150 members, many of whom are well known to the scientific world. The Society's efforts to carry out the objects for which it was established have been, on the whole, successful. Of the papers printed *in extenso*, a series of twenty letters forming a most interesting correspondence between Gilbert White and Robert Marsham, is by far the most important. This is rendered still more interesting by the valuable notes contributed by Mr. Harting and Prof. Newton. Of the other original papers, we may mention the Meteorological Report and the Ornithological Report, by Henry Stephenson, F.L.S. (author of the "Birds of Norfolk"); also the concluding portion of Mr. Geldart's list of the plants known to occur in Norfolk. The latter forms a portion (the sixth) of the Fauna and Flora of the County, which the Society is printing. Among the occasional notes and observations some interesting facts are recorded.

LIEUT. MINTZER, of the U.S. Navy, we learn from *L'Explorateur*, is organising a scientific expedition to the Arctic Seas, at Norwich, Connecticut.

A VERY destructive earthquake was felt at Corinth (Greece) on June 26, and another of the same date in Austria.

AT the Loan Collection during the present week, twelve demonstrations of apparatus were given on Monday, the same number on Tuesday, and six on Wednesday; four will be given to-day, four to-morrow, and ten on Saturday.

TWO handsome works have just been published by Masson of Paris—"Le Microscope, son Emploi et ses Applications," by Dr. J. Pelletan, with 278 figures and four plates, and "Traité d'Électricité Statique," by Prof. E. Mascart, two vols., with 298 figures.

PETERMANN'S *Mittheilungen* for June contains a considerably detailed account of the results of the discovery of Franz-Josef Land by the Payer-Weyprecht Expedition, founded on the work recently published at Vienna by Lieut. Payer. Accompanying the paper is the first satisfactory map yet published of the newly-discovered land, in which all the details of the sea and land are shown, as well as all the names imposed by the leaders of the expedition. Dr. Couto de Magalhães' "Travels in Araguaya" are concluded, and a brief synoptical summary is given of Walker's new statistical atlas of the United States.

THE Lindley Library, to which we referred last week (p. 200), does not belong to the Horticultural Society, nor was it bought by it. It was purchased with part of the surplus of the proceeds of the International Horticultural Exhibition and Botanical Congress held in London in 1866, and is vested in the hands of sundry trustees, who will be grateful for any donation. By permission of the Horticultural Society the library is deposited in its rooms.

THE twenty-eighth annual meeting of the Somersetshire Archæological and Natural History Society will be held at Bath on July 18, 19, and 20, under the presidency of Mr. Jerom Murch. Several excursions have been arranged.

THE first aquarium erected in Scotland was opened at Rothesay, in the island of Bute, last Thursday. The situation of the aquarium is in every respect favourable, and there is a large amount of tank accommodation, which has been arranged so as to contain both salt and fresh-water fish. The fresh-water tanks are perhaps the largest of the kind in the country, one of them containing over 20,000 gallons of water. A seal-pond is being constructed, and an eight-horse power engine sends the fresh and salt water from the reservoirs below to the tanks above. The reservoir for the former is capable of containing 90,000 gallons, while that for the latter has a capacity of 150,000 gallons. It is hoped that the aquarium will do good service as a school for practical natural history.

VARIOUS sanitary measures (according to Dr. Tholozan) have recently been adopted by the Turkish and Persian Governments with reference to the outbreak of plague, which commenced in Mesopotamia in the early part of the year. Since the beginning of March a sanitary *cordon* has been established on the north of the invaded territory, on the most frequented route of Kurdistan and Syria, between Tecrit and Kifri. On the south a quarantine of fifteen days is obligatory since April 1 on all vessels sailing on the Tigris and the Euphrates. It is at Kourna, at the confluence of these rivers. The ports of the Persian Gulf are protected by a quarantine which vessels from infected localities have to undergo at the island of Kezzer, formed by junction of the Chotel Aral and the Karoun. Since April 10 all communications by land between Persia and Mesopotamia are subject to a quarantine of fifteen days. For three years, it may be added, all pilgrimages into the infected country, by Persian subjects, have been interdicted. To fully comprehend this system of protection it should be remembered that on the west and north-west, for an extent of three degrees of latitude, no artificial barrier has been or can be established against the plague; but there are, happily, natural obstacles, which prove much more efficacious, the infected region being there bounded by the deserts of Syria and Mesopotamia. The greater rarity of communications there renders restrictive measures, on the arriving caravans, easier. Judging from past outbreaks of plague, it was anticipated that the present would decline in June (after reaching its *acme* in the end of May), and disappear from Mesopotamia in July. But it may send off-shoots to Bussora, Bouchéïe, and Arabistan, and a still greater danger is the introduction of germs of the plague into the high plateaux of Anatolia, Kurdistan, and Persia.

AN interesting addition to the literature of insectivorous plants is furnished by a reprint, by Casimir De Candolle, from the *Archives des Sciences Physiques et Naturelles*, "Sur la Structure et les Mouvements de Feuilles de *Dionæa muscipula*." With regard to the power of digestion, M. De Candolle comes to a conclusion opposed to that of Darwin, that the absorption of animal substances is not directly utilised by the leaves, and is not necessary to the development of the plant. He considers their anatomical structure favourable to the hypothesis that the movement of the two valves of the leaf results from variations of turgidity of the parenchyma of their upper surface.

A SINGULAR and useful society is in the way of formation at Paris. Seventy-two institutions of France have met in the Hotel of the rue de Grenelle to organize a general topographical association. Each institution becoming a member engages to prepare a topographical map of its commune, with roads, streams, mountains, &c. As the number of institutions in France exceeds 40,000, the number of registered adherents is very small indeed; but more are expected to join, especially if the Government takes interest in the association. The scientific value of such maps may not be great, but the result in the diffusion of geographical methods and promotion of knowledge is unquestionable.

CAPT. ROUDAIRE has delivered before the Geographical Society of Paris a lecture on the results of the survey of the Tunisian

Chotts. The measures taken last year on the Algerian side have been verified. The same level has been found for the connecting station with an immaterial difference of 2·80 metres in favour of the operation. The altitude at Gabes is only 46 metres, which is no obstacle to the channel being opened. Every objection raised by an Italian Commission has been set aside. MM. d'Abbadée and de Lesseps promised their help and testified their satisfaction.

THE half-yearly general meeting of the Scottish Meteorological Society will be held to-morrow. The business before the meeting will be—1. Report from the Council of the Society. 2. Notice as to observations of the velocity of the wind at different heights, by Thomas Stevenson, F.R.S.E., F.G.S. 3. Meteorological Register kept by James Hoy, at Gordon Castle from 1781 to 1827, communicated to the Society by His Grace the Duke of Richmond and Gordon, with remarks thereon by Mr. Buchan, secretary. This, we believe, is a very valuable register.

MR. E. F. FLOWER has published "A Sequel" to his much-needed pamphlet on "Bits and Bearing Reins." We are glad to see that his efforts to abolish the useless and cruel bearing-rein, and to introduce a rational and humane, and therefore scientific, way of managing horses has been largely successful. We cannot see how any man who wishes to be "merciful to his beast" can, after reading Mr. Flower's pamphlet, persist in the use of the bearing-rein, which after all is quite unnecessary, and no doubt tends to make a horse contract vices.

NOS. 4 and 5 of the *Iowa Weather Review* give a very good summary of the weather of the State of Iowa during December, January, and February last, dividing the season into nine decades. The winter was unusually mild, being 10°·5 above the average of Iowa winters, while during the third decade of December the excess rose to 19°·7. Less than an inch of rain fell in the north-west of the State, but in the central countries the fall was large, amounting to 9·60 inches at Davenport. Several interesting practical tables are added showing the days of thaw when the maximum exceeded 32°, days of frost when the minimum fell below 32°, and days of cold when the temperature fell to zero or lower. Sudden colds following in the wake of storms are also detailed, together with the barometric rise, and the velocity and direction of the wind, accompanying these great falls of temperature, which form so marked a feature in the climate of America. The alleged change of climate from the cultivation of the soil and the destruction of forests by which the summers, as stated, are becoming warmer and the winters colder, is a question which deserves to be carefully examined.

WE have received "Results of Meteorological Observations made at the Bath Royal Literary and Scientific Institution during the Ten Years ending February, 1875," by the Rev. Leonard Blomefield. The pamphlet, which is an extract from the "Proceedings of the Bath Natural History and Antiquarian Field Club," is a conscientious piece of work, evidently got up with the greatest care. The instruments appear to be fairly placed, except the rain-gauge, which is fixed in a faulty position, viz., at the top of a building. The monthly and yearly mean temperatures have been deduced from the 9 A.M. observations corrected for diurnal range, though it may well be doubted whether "*means*" can be calculated from observations made at only one hour of the day and whether any diurnal range corrections yet exist applicable to Bath. Some very interesting comparisons are drawn between the climate of Bath and other parts of England, with on the whole a just apprehension on the part of the author of the misleading nature of data when based on the observations of different years. Some of the differences, however, pointed out by Mr. Blomefield, such as the higher temperature of Bath as compared with Exeter during January and February disappear when a comparison is made from observations taken during the same years at each place, or from results obtained by the method of differentiation. Among the interesting results arrived at is the higher temperature of the river as compared with that of the air at Bath amounting to 2°·5 on a mean of the year, rising in June to 4°·6, and falling in February to 0°·5. In many respects the pamphlet is a valuable contribution to the meteorology of the south-west of England.

DR. H. HAMBERG, Assistant Professor of Meteorology at the University of Upsal, has written in the "Proceedings of the Royal Academy of Sciences," Stockholm, a very interesting paper on the development of the barometric minimum accompanying the thunderstorms which occurred in Sweden and Norway from July 14 to 20, 1872. From the data before him, Dr. Hamberg concludes that the barometer fell most where the sky was cloudless, and that the fall of heavy rain was generally attended with a rise rather than a fall of the barometer, much in the same way as Dr. Hann has shown to take place within the tropics at Batavia. The question is as difficult as it is important in meteorology, and the investigation of the behaviour of the barometer during our summer thunderstorms is likely to lead to most valuable results.

THE additions made to the Royal Aquarium, Westminster, during the past week are as follows:—A large collection of fresh-water fish, including Carp, Bream, Chub, Perch, Roach, and Trout, presented by the Earl of Aylesford; Sand-eels (*Ammodytes lancea*), Gemmeous Dragonettes (*Callionymus lyra*), Lump-fish (*Cyclopterus lumpus*), Five-bearded Rocklings (*Motella mustela*), Sea Bream (*Cantharus lineatus*), a shoal of young Lobsters (*Homarus vulgaris*), hatched in the tanks.

THE additions to the Zoological Society's Gardens during last week include eleven Lineated Pheasants (*Euplocamus lineatus*), nine Amherst Pheasants (*Thaumalea amherstiæ*), nine Gold Pheasants (*T. picta*) and two Peacock Pheasants (*Polyplectron chinquis*), bred in the Gardens; a Cape Buffalo (*Bubalus caffer*).

SCIENTIFIC SERIALS

THE January number of Reichert and Du Bois-Reymond's *Archiv* opens with the conclusion of L. Dittmer's lengthy communication on double monsters.—Carl Sachs describes and figures the terminations of nerve fibres in certain tendons.—In a long controversial article, Prof. Hitzig defends his own and Fritsch's conclusions with respect to the functions of the cerebrum against Hermann, Braun, Carville, and Duret.—F. Boll's article on the Savian vesicles found in the torpedo about the nasal orifices and between the external edges of the electrical organs and the limb-cartilages, is very interesting, because he demonstrates the existence in their epithelium of spindle-shaped cells corresponding in character to those so commonly found in special sense organs.—Dr. Colasanti, of Rome, gives an account of the results of section of the olfactory nerve in the frog. He finds that there is no consequent alteration in the nutrition or appearance of the olfactory cells or of the peripheral ramifications of the pale nerve-fibres.—Dr. Colasanti, in another short memoir shows that the fertilised hen's egg may be reduced in temperature to from − 7° to − 10° C. without its vitality being destroyed or in any way interfered with.—Rabl-Ruckhard contributes an elaborate account of the brain and cerebral nerves of the black ant (*Camponotus ligniperdus*).

The March number of the *Archiv* contains a very interesting account by P. Guttmann of his new experiments on respiration. Investigating the respiratory pause following on inspiration, he found that in vagotomised rabbits this pause does not occur. The possible reasons for this are discussed. In rabbits, in whom apnœa has been produced, it is always found that when the apnœa terminates, an inspiration, not an expiration, is the first phenomenon.—Bernstein and Steiner contribute an important paper on the transmission of contraction and the negative variation in the muscles of mammalia; but the intricacy of the sub-

ject does not admit of a brief abstract.—Another valuable paper on this subject, by Du Bois-Reymond himself, is commenced in this part. It constitutes the second part of his researches on negative variation of the muscular current during contraction, and must be consulted by all workers in this difficult branch of research.—Dr. Wenzel Grüber has five papers, some of considerable length, on various anomalous muscular dispositions. Such papers should be condensed as much as possible.

THE two last numbers of the *Nuovo Giornale Botanico Italiano* are chiefly occupied with Italian botany.—Among papers of more general interest we have a description by A. Mori, of the structure of the wood of *Periploca græca*; and two by Prof. Caruel:—On the flowers of *Ceratophyllum*, in which he describes the peculiar contrivance for the fertilisation of the female flowers, the rigid leaves apparently serving as the channel of transport for the pollen; and observations on *Cynomorium*, in which several points in the structure of the flower are detailed, and the author gives his adhesion to Dr. Hooker's suggestion of a possible genetic connection between Balanophoreæ and Halorageæ.

Zeitschrift der Oesterreichischen Gesellschaft für Meteorologie, March 15.—The first article is by Prof. Tomaschek, of Brünn, on mean temperatures as thermal constants for vegetation. The law, formerly pointed out by him, of the dependence of the commencement of blooming, on the height of daily mean temperatures, appears not only not to be shaken, but to be supported by an investigation of the results for the exceptional year 1862.—The next article is by Dr. Hann, on the results of observations on Mount Washington and Pike's Peak. During very cold weather, the change of temperature with height is less than usual, amounting only to about 0·3° C. for each 100 metres, so that the equilibrium of the air vertically must be at such times very stable. The mean decrease with height in the dry climate of Pike's Peak is somewhat greater than in the Alps and at Mount Washington. The daily and monthly ranges are excessive on the elevated plains. Dr. Hann greatly regrets the impracticable form in which the reports have been published, considering the desirability of having the actual observations for Pike's Peak and Colorado Springs, two stations better situated for meteorological purposes than any others in the world, accompanied by the proper data and corrections, which are here wanting.—In the Kleinere Mittheilungen we find a description of Redier's self-registering barometer.

Journal de Physique, February.—This number commences with the first part of a paper by M. Jamin, describing his recent researches on magnetism. He gives an account of his methods of observation, offers some theoretical ideas on the nature of magnetism, and discusses magnetic conductivity and distribution in a thin plate.—In a note on meteorology applied to agriculture, M. Marié Davy gives some interesting tables with reference to changes observed in wheat at different dates (the relation of transpired water to the temperature and actinometric degree, the weight of constituent substances, proportion of nitrogen in stalk, &c.). He considers that by the end of May or beginning of June, according to locality, one may generally deduce from meteorological data the probable value of the coming harvest, save in the case of exceptional perturbations, whose injurious action is circumscribed.—M. Duter investigates the distribution of magnetism in circular and elliptical steel plates.

Gazzetta Chimica Italiana, 1876, fascicolo ii.—This part commences with a paper by G. Pisati in continuation of former researches entitled:—On the elasticity of metals at different temperatures. In this paper the author treats of the elasticity of torsion at various temperatures of wires of silver, iron, steel, copper, brass, gold, platinum, and aluminium. The apparatus employed is figured, and the results shown in many cases graphically by means of curves.—On the production of ozone during the evaporation of water, by G. Bellucci.—The modifications of starch in plants, by M. Mercadante.—Synthesis of propyl-isopropyl-benzene, preliminary note by E. Paterno and P. Spica. This hydrocarbon, of which the formula would be $C_6H_4 \left\{ \begin{array}{l} C_3H_7 \\ CH_2.C_2H_5 \end{array} \right.$ has been prepared by the action of zinc ethyl on cumene chloride. It is a liquid a little lighter than water boiling at about 205°—208°. Other hydrocarbons boiling at a high temperature are also produced during the reaction. The authors propose to continue their researches.—The absence of leucine in the product of the germination of graminaceæ, by M. Mercadante.—The remainder of the part is devoted to abstracts of papers from foreign sources.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, June 15.—"Researches illustrative of the Physico-Chemical Theory of Fermentation, and of the conditions favouring Archebiosis in previously Boiled Fluids." By H. Charlton Bastian, M.A., M.D., F.R.S., Professor of Pathological Anatomy in University College, London, and Physician to University College Hospital.

The author first calls attention to the fact that no previous investigator has professed to have seen well-marked fermentation set up in urine that had been boiled for a few minutes, if it has thereafter been guarded from contamination. The previous invariable barrenness of this fluid after boiling has been ascribed by germ-theorists to the fact that any organisms or germs of organisms which it may have contained were killed by raising it to the temperature of 212° F. (100° C.).

In executing some of the experiments with urine described in this communication, two chemical agents have been brought into operation under novel conditions, and an ordinary physical influence has been employed to an entirely new extent. In several respects, therefore, these new experiments differ much, as regards the conditions made use of, from those hitherto devised for throwing light upon the much-vexed questions as to the possible origin of Fermentations independently of living organisms or germs, and as to the present occurrence or non-occurrence of Archebiosis.

The chemical agents employed under new conditions in these experiments were *liquor potassæ* and *oxygen*—both of them being well known as stimulants, if not as promoters, of many fermentative processes.

It has been recognised by several investigators of late years that neutral or slightly alkaline organic fluids are rather more prone to undergo fermentation than slightly acid fluids. This fact may be easily demonstrated. As the author pointed out in 1870, if two portions of an acid infusion are exposed side by side at a temperature of 77° F. (25° C.) fermentation may be made to appear earlier and to make more rapid progress in either of them by the simple addition of a few drops of liquor potassæ; on the other hand, if a neutral infusion be taken and similarly divided into two portions placed under the same conditions, fermentation may be retarded, or rendered slower in either of them at will, by the simple addition to it of a few drops of acetic or some other acid.

A neutral or faintly alkaline organic solution can in this way be demonstrated to possess a higher degree of fermentability than an otherwise similar acid organic solution. It seems, therefore, obvious that the changes capable of taking place in *boiled* acid and neutral solutions respectively should also vary considerably. Numerous experiments by different observers have demonstrated the correctness of this inference. Boiled acid infusions guarded from contamination mostly remain pure and barren if kept at temperatures below 77° F. (25° C.), though other infusions similarly treated and similar in themselves, except that they have been rendered neutral by an alkali, will oftentimes become corrupt and swarm with organisms. The latter result follows still more frequently with neutral infusions when they are exposed to a higher generating temperature in the warm-air chamber; and under this stronger stimulus a small number of boiled acid fluids will also ferment.

On the other hand, the influence of oxygen in promoting fermentation has been fully appreciated since the early part of the present century. Formerly an influence was assigned to it as an initiater of fermentation as all-important as some chemists assign to living germs at the present day. But this was a very exaggerated view. In some fluids, as the author has shown, fermentation may be initiated just as freely, or even rather more so, in closed vessels from which the air has been expelled by boiling, as in others in which atmospheric air, and consequently oxygen, is present. The explanation of this fact is probably to be found in the supposition that, in starting the fermentation of these fluids, diminution of pressure may be of as much, or even of more importance than contact with free oxygen. In respect to other organic fluids, however, the influence of oxygen seems decidedly more potent as a co-initiater of fermentation than that diminution of pressure which is brought about by hermetically sealing the vessel before the fluid within has ceased to boil. Urine will be found to be an example of this latter class of fluids.

The physical influence which has been employed in unusual intensity in the present researches is *heat*.

Previous experimenters have never designedly had recourse to a generating or developing temperature above 100° F. (38° C.). The heat employed has frequently been below 77° F. (25° C.), though a temperature between this and 95° F. (35° C.) has been regarded both by chemists and biologists as most favourable to the occurrence and progress of fermentative changes generally.

Early in the month of August, 1875, the author ascertained the fact that some boiled fluids which remained barren when kept at a temperature of 77°–86° F. (25°–30° C.) would rapidly become turbid and swarm with organisms if maintained at a temperature of 115° F. (46° C.). More recently he has discovered the surprising fact that a generating temperature as high as 122° F. (50° C.) may be had recourse to with advantage in dealing with some fermentable solutions. Fluids which would otherwise have remained barren and free from all signs of fermentation have, under the influence of this high temperature, rapidly become turbid and corrupt. This discovery is regarded as of great importance in reference to the questions now under discussion, and it is one which was quite unexpected. The author had previously shared in the generally received opinion that temperatures above 100° F. (38° C.) were likely to impede rather than promote fermentation.

In maintaining the experimental fluids at the high temperature above-named, the vessels containing them were placed in the hot-air chamber of an incubator, such as physiologists employ, to which one of the very ingenious gas-regulators of Mr. F. S. Page had been fitted (see *Journal of the Chemical Society*, January, 1876). In this way the fluids may be kept at a known and practically constant temperature for an indefinite time.

Liquor Potassæ as a Promoter of Fermentation in Boiled Urine.

In the autumn of 1875 the author instituted some experiments to ascertain whether the fermentability of boiled urine, like that of many other fluids, could be increased by previously mixing with it a quantity of liquor potassæ sufficient for its neutralisation.

The experiments answered this question in the affirmative. It was found that urine to which the above-named amount of liquor potassa had been added, would constantly ferment and swarm with organisms within a few days after it had been boiled; though some of the same stock of urine in the acid state (that is, without the addition of any alkali) would when similarly treated in other respects, remain barren. The fact of the production of an increased fermentability in boiled urine by previous neutralisation was thus established.

Further experiments were then instituted to throw light upon the cause of such increased fermentability. It was desirable to ascertain whether (1) it was due to survival of germs in the boiled neutralised fluid, or (2) to the chemical influence of potash in initiating or helping to initiate the molecular changes leading to fermentation in a fluid devoid of germs or other living matter.

The mode of testing the relative validity of these rival interpretations seemed easy. It was only necessary to ascertain what the effect would be of adding boiled liquor potassæ, in proper quantity, after the acid urine had been rendered barren by boiling it instead of adding it previous to the process of ebullition. If fermentation occurred in the fluid thus neutralised without extraneous contamination, the first interpretation would obviously be negatived.

This crucial experiment was at first tried with flasks plugged with cotton-wool, the plug in each of them being penetrated by a closed glass tube containing the measured amount of liquor potassæ. The tubes having been drawn out to a capillary portion at the lower end, and bent at an obtuse angle, they could be easily broken by slight downward pressure against the bottom of the flask whenever it was desired to mix the liquor potassæ with the boiled urine. This apparatus was very similar to that first made use of by Dr. William Roberts in some experiments with hay-infusion (Phil. Trans. vol. clxiv. p. 474), in which he obtained opposite results from those now about to be recorded with urine. The latter fluid is, however, for several reasons more suitable than hay-infusion for trying such experiments.

Several trials made with urine in this apparatus showed that its fermentability was just as much increased by adding boiled liquor potassæ after the urine had been boiled in the acid state, as by adding the alkali previous to the process of ebullition. Such a result was therefore quite opposed to the first interpretation as to the cause of the increased fermentability of neutralised urine.

The definite overthrow or establishment of this interpretation was so important that it seemed desirable to try such experiments again by some more rigid and certain method. The author, therefore, devised a new mode of experimentation in which scaled retorts replaced the flasks plugged with cotton-wool, and in which the contents of the enclosed liquor-potassæ tubes could be more effectually heated.

It was first of all ascertained that accurately-neutralised urine boiled in a retort and sealed whilst boiling, would ferment in a day or two if kept at a temperature of 122° F.[1]

This fact having been established, other retorts were charged with a measured amount of urine, and also with a small glass tube containing liquor potassæ in quantity almost sufficient to neutralise the urine employed.[2] The glass tubes containing the liquor potassæ had been drawn out at one end, sealed, and then immersed in boiling water for different periods before introducing them into the retorts. After each retort had been charged with urine and a liquor potassæ tube, its neck was drawn out to a capillary point, the urine was boiled, and the retort was hermetically sealed before ebullition had ceased. Thus closed, the vessel was at once immersed with its neck downwards in a can of boiling water for from four to fifteen minutes, so as to expose it and its contents for an additional period to a temperature of 212° F. (100° C.).

The urine was thus boiled in its unaltered acid state and sterilised. After the retorts had cooled the liquor potassæ was liberated from its tube in all but one of the batch, which was kept as a control experiment. The liberation was easily effected. It was only necessary to give the retort a sudden shake so as to drive the capillary neck of the enclosed tube against its side. The tube was thus broken and immediately (owing to the comparative vacuum within the retort) the liquor potassæ was sucked out and mixed with the fluid which it was destined to neutralise.

The result of these experiments was similar to those executed with the plugged flasks and liquor-potassæ tubes. The boiled caustic potash added afterwards within the sealed retorts, caused the previously barren fluids to ferment and swarm with *Bacteria*. The fluid in the control experiment remained pure, though after several days, or longer, it also could be made to ferment by breaking the liquor-potassæ tube, and replacing the retort in the warm chamber.

Effects of liberating Oxygen by Electrolysis within the Closed Retorts. A few other experiments were made with retorts to which platinum electrodes had been fitted. These contained, as before, measured amounts of urine, together with liquor potassæ tubes. All the preliminary stages were similar to those of the experiments above recorded; but just before breaking the liquor-potassæ tubes in these further experiments, oxygen and hydrogen were liberated from the boiled urine by electrolysis.

The result in the few experiments made was very remarkable. Under the combined influence of liquor potassæ, oxygen, and the high temperature of 122° F. (50° C.), the sterilised urine fermented and swarmed with *Bacteria* within the closed retorts in from 7–12 hours—that is, in a much shorter time than would suffice for the occurrence of similar changes in unboiled urine freely exposed to the air.

Behaviour of some Specimens of unaltered Acid Urine under the influence of the High Generating Temperature of 122° F. (50° C.).

In the course of the previous experiments it was found that occasionally a specimen of boiled urine would ferment at a temperature of 122° F. without the addition of liquor potassæ. This was afterwards ascertained to occur invariably (with the urine experimented upon) when the acidity of the fluid was not higher than would be represented by six minims of liquor potassæ to the ounce (or about 1½ per cent.). Urines slightly more acid than this sometimes did and sometimes did not ferment without liquor potassæ; but when the acidity exceeded what would be equivalent to two per cent. of liquor potassæ, the fluid did not ferment under the influence of the high generating temperature alone. Urines of all degrees of acidity, however, were found to ferment under the combined influence of heat and liquor potassæ added afterwards, in the manner already detailed.[3]

[1] Though the boiled urine will ferment in retorts from which the air has been expelled by boiling, it will undergo this change more quickly if it is in the presence of purified or sterilised air. In the experiments now about to be described, however, it was much more convenient to use airless retorts.

[2] As a slight excess in the amount of liquor potassæ has been proved to have a most restrictive influence when dealing with urine, it was found safer in these experiments not to provide liquor potassæ sufficient for full neutralization. Many details on this subject are given in the memoir itself.

[3] In the urine of highest acidity with which experiment has been made, twenty minims of liquor potassæ to the fluid ounce (about 4 per cent.) was required for neutralisation.

It was further ascertained that the acidity of some specimens of urine was lessened during the process of ebullition (owing to the deposition of acid phosphates); and such urines boiled for six minutes were found to ferment in a much shorter time than when they were only boiled for three minutes. The prolongation to this extent of the germ-destroying temperature actually hastened the subsequent process of fermentation.

Interpretation of Results.

The generally received belief that all *Bacteria* and their germs are killed by exposing them even for a minute or two to the temperature of 212° F. (100° C.) has of late been strongly reinforced by Prof. Tyndall. The fact, therefore, of the fermentation of some specimens of boiled acid urine, with the appearance of swarms of *Bacteria*, under the influence of the high generating temperature of 122° F. (50° C), is inexplicable except upon the supposition that fermentation has in these instances been initiated without the aid of living germs, and that the organisms first appearing in such fluids have been evolved therein.

If the author's further position (Proceedings of Royal Society, Nos. 143 and 145, 1873), that *Bacteria* and their germs are killed in fluids whether acid or alkaline at a temperature of 158° F. (70° C.), is correct, then the occurrence of fermentation in the previously neutralised boiled urine would similarly disprove the exclusive germ-theory of fermentation and establish the occurrence of Archebiosis.

Any difficulty which might have been felt by others in accepting the above interpretation of the results of these latter experiments—in face of the view held by M. Pasteur that some *Bacteria* germs are able in neutral fluids to survive an exposure to a heat of 212° F. (100° C.)—has been fairly met and nullified by the experiments (devised for the purpose), in which the urine was boiled in the acid state and subsequently fertilised by the addition of boiled liquor potassæ.

If we look at these latter experiments from an independent point of view, it will be found that this fertilisation of a previously barren fluid by boiled liquor potassæ must be explained by one or other of three hypotheses:—

1st Hypothesis. The boiled liquor potassæ may act as a fertilising agent because it contains living germs.—However improbable this hypothesis may seem on the face of it, it has been actually disproved by many of the experiments recorded in this memoir. These experiments show that boiled liquor potassæ will only act as a fertilising agent when it is added in certain proportions. If it acted as a mere germ-containing medium, a single drop of it would suffice to infect many ounces, a gallon, or more of the sterilised fluid. This, however, is never the case; it only fertilises the barren urine when it is added in a proportion dependent upon the precise acidity and quantity of the fluid with which experiment is being made.

2nd Hypothesis. The fertilising agent may act by reviving germs hitherto presumed to have been killed in the boiled acid urine.—The acceptance of this hypothesis would involve a general recantation of the previously received conclusion that *Bacteria* and their germs are killed by boiling them in acid fluids. But such a recantation would be scarcely justifiable or acceptable unless based upon good independent evidence.

The possibility, however, of accepting this second hypothesis is still further closed by the results of experiments in which a slight excess of liquor potassæ was added to the boiled urine. Such fluids invariably remained barren. Yet it can be easily shown that the mere development and growth of *Bacteria*-germs may take place both quickly and freely in boiled urine containing a very large excess of liquor potassæ.[1] It would seem that this agent mixed with boiled urine in quantity slightly more than is needed for neutralisation, prevents the *origination* of living matter therein, although even when in considerable excess the same agent affords no obstacle to the development, growth, and multiplication of germs purposely added thereto.

In the face of these facts it would seem impossible to accept this second hypothesis, even if it had not been independently negatived by the great mass of evidence—lately reinforced by the experiments of Prof. Tyndall—to the effect that *Bacteria* and their germs are really killed in fluids raised for a few minutes to the boiling-point (212° F.).

3rd Hypothesis. The fertilising agent acts by helping to initiate chemical changes of a fermentative character in a fluid devoid of living organisms or living germs.—If the cause of the fermentation of the fluids in question does not exist in the form of living organisms or germs either in the fertilising agent itself or in the medium fertilised, then it must be found in some chemical reactions set up between the boiled liquor potassæ and the boiled urine.

[1] A mixture of one part of liquor potassæ to seven of boiled urine poured into a bottle which has been washed with ordinary tap-water will, within forty-eight hours, swarm with *Bacteria* if it is kept at a temperature of 122° F.

The experiments in which liquor potassæ is added to urine in definite proportions before and after it has been boiled with the result of inducing fermentation in the otherwise barren fluids, as well as those in which unaltered urine ferments under the influence of the high generating temperature of 122° F. (50° C.), all alike, therefore, point to the same conclusion. They show, as other experiments have done, that an exclusive germ-theory of fermentation is untenable; and they further show that living matter may and does originate independently during the progress of fermentation in previously germless fluids.

As a result of the fermentative changes taking place in boiled urine or other complex organic solutions, many new chemical compounds are produced. Gases are given off, or these with other soluble products mix imperceptibly with the changing and quickening mother-liquid, in all parts of which certain insoluble products also make their appearance. Such insoluble products reveal themselves to us as specks of protoplasm, that is of "living" matter. They gradually emerge into the region of the visible, and speedily assume the well-known forms of one or other variety of *Bacteria*.

These insoluble particles would thus in their own persons serve to bridge the narrow gulf between certain kinds of "living" and of "dead" matter, and thereby afford a long-sought-for illustration of the transition from chemical to so-called "vital" combinations.

Zoological Society, June 20.—Prof. Flower, F.R.S., vice-president, in the chair.—The Secretary exhibited a drawing of a fine species of Fruit-Pigeon of the genus *Carphophaga*, living in the Society's Gardens, which apparently belonged to *C. paulina*, Bp. of Celebes and the Sulu Islands.—Mr. Sclater read extracts from letters received from Signor L. M. D'Albertis and Dr. George Bennett, respecting M. D'Albertis' proposed new expedition up the Fly River, New Guinea, and exhibited a small collection of bird skins made at Yule Island and on the adjoining coast of New Guinea, by the last-named naturalist.—Dr. A. Gunther, F.R.S., read a letter from Commander W. E. Cookson, R.N., respecting the large tortoises obtained in the Galapagos Islands which had been recently deposited in the Society's Gardens by Commander Cookson. The living specimens had been obtained in Albemarle Island, those obtained in Abingdon Island having died before reaching this country. Dr. Gunther added some remarks on the specimens of tortoises and other animals collected by Commander Cookson, and promised a more detailed account on a future occasion.—Mr. G. E. Dobson read a paper on peculiar structures in the feet of certain species of mammals by which they are enabled to walk on smooth perpendicular surfaces, especially alluding to *Hyrax* and the bats of the genus *Thyroptera*.—A communication was read from Dr. J. S. Bowerbank, F.R.S., being the sixth part of his monograph of the silicio-fibrous sponges.—A communication was read from the Rev. O. P. Cambridge containing a catalogue of a collection of spiders made in Egypt, with descriptions of new species and characters of a new genus.—A communication was read from Mr. W. T. Blanford containing remarks on the views of A. von Pelzeln as to the connection of the faunas of India and Africa, and on the mammalian fauna of Tibet.—A second communication from Mr. W. T. Blanford contained remarks on some of the specific identifications in Dr. Günther's second report on collections of Indian reptiles obtained by the British Museum.—Mr. Howard Saunders read a paper on the *Sterninæ* or Terns, with descriptions of three new species, which he proposed to call *Sterna tibetana*, *Sterna eurygnatha*, and *Gygis microrhyncha*.—Dr. Cunningham, of the University of Edinburgh, described a young specimen of a dolphin, caught off Great Grimsby, in September, 1875. After pointing out the great difficulty experienced in referring it to its proper place amongst the dolphins—this difficulty arising chiefly from the unsatisfactory and even unreliable descriptions which have been given in this country by former observers—he came to the conclusion that he was justified in referring it to *Delphinus albirostris*, the differences being, in his opinion, merely those of age.—Mr. J. W. Clark read some notes on a dolphin lately taken off the coast of Norfolk, which he was likewise induced to refer to the same species.—A

communication was read from Mr. R. B. Sharpe, containing the description of an apparently new species of owl from the Solomon Islands, which he proposed to call *Ninox solomonis*.—Mr. A. H. Garrod some notes on the anatomy of certain parrots.—Mr. H. E. Dresser read the description of a new species of broad-billed sandpiper, from North-Eastern Asia, to which he gave the name *Limicola sibirica*.—A second communication from Mr. Dresser contained the description of a new species of *Tetraogallus*, discovered by Mr. Danford in the Cilician Taurus, which he proposed to call *T. tauricus*.—Dr. A. Günther read some notes on a small collection of animals brought by Lieut. L. Cameron, C.B., from Angola.—A communication was read from Lieut. R. Wardlaw Ramsay, giving the description of a fine new species of Nuthatch from Karen-nee, which he proposed to call *Sitta magna*.

Meteorological Society, June 21.—Mr. H. S. Eaton, M.A., president, in the chair. The following papers were read:—On the climate of Scarborough, by F. Shaw. The thermometers used were placed in a louvre-boarded case fixed to the north side of a wooden structure, having an open grass plot in front of them. The garden is about midway between the north and south sides of the town, and 150 yards from the shore; and as both residents and visitors are continually passing along this line, the observations may be taken as fairly representing the temperature of Scarborough as a watering-place. The mean monthly temperatures based on the average of the past eight years are:—

Jan., 38°·8	April, 46°·6	July, 60°·4	Oct., 48°·2
Feb., 39°·7	May, 50°·5	Aug., 58°·9	Nov., 42°·2
Mar., 41°·6	June, 55°·9	Sept., 55°·1	Dec., 39°·0

The mean for the year is 48°·1.

The maximum temperature on any day in July, the warmest month, does not exceed on the average, 78°·0; the highest in the eight years being 85°·5 in 1868. The mean of the extreme minimum temperature in the eight Januarys is 24°·2; the lowest being 13°·3, which occurred on January 1, 1875. The moderate and agreeable summer temperature is due to the close proximity of the town to the sea, which in the warmest month of the season is about 5° below that of the air. The autumn and winter temperatures are also much influenced by the sea on the one hand, and the shelter afforded by the surrounding hills on the other. The sea is about 5° warmer than the air in the autumn, and 3° in the winter, while the prevailing winds are south-westerly and not felt in their full force. The annual rainfall, on the average of the past ten years, is 28·29 inches, which falls on 167 days.—Notice of upward currents during the formation and passage of cumulus and cumulo-stratus clouds, by Rev. J. Crompton. On Nov. 1, 1866, the day after the visit of the Prince and Princess of Wales to Norwich, when the city was profusely decorated with flags, the author, when walking close to the cathedral, was struck with the unusual fluttering of the flags on the top of the spire, which is 300 feet high. They were streaming with a strained, quivering motion, perpendicularly upwards. A heavy cloud was passing overhead at the moment, and as it passed the flags followed the cloud and then gradually dropped into comparative quietness. The same phenomenon was noticed several times. As the cloud approached, the upper banners began to feel its influence, and streamed towards it against the direction of the wind, which still blew as before, steadily on all below; as the cloud came nearer the vehement quivering and straining motion of the flags increased, they began to take an upward perpendicular direction right into the cloud, and seemed almost tearing themselves from the staves to which they were fastened; again, as the cloud passed they followed it as they had previously streamed to meet its approach, and then dropped away as before, one or two actually folding over their staves. All the other flags at a lower elevation did not show the least symptom of disturbance.—Suggestions on certain variations, annual and diurnal, in the relation of the barometric gradient to the force of the wind, by Rev. W. Clement Ley. The author finds that the mean velocity of the wind corresponding to each gradient is much higher in summer than in winter. This is the case at all stations (though not equally) with all winds, with all lengths of radius of isobaric curvature, and with all values of actual barometric pressure. The general character of the mean diurnal variations of velocity, as these occur at the stations in the British Isles, may be fairly inferred from mean horary velocity curves, and may be thus described:—At the inland stations, in summer, a slight increment of velocity occurs about midnight. This is succeeded by the morning minimum, which takes place in most of the months examined a little after sunrise. The mean velocity then rises until 1 P.M., when the diurnal maximum is sometimes attained. A slight subsidence then commonly occurs, but the mean velocity rises again at 3 or 4 P.M., and this second increment frequently forms the diurnal maximum. A great fall then takes place, which is more rapid than the rise in the morning; and the evening minimum, which is in most months the diurnal minimum, is attained about 10 P.M. The mean velocity at 1 P.M. is, in fine and hot weather, more than double the 10 P.M. velocity in miles per hour, and exceeds the diurnal mean by about one-third. In winter the inflexions are very greatly modified. The midnight rise is not in all months traceable, and the subsequent diminution is not very great. The morning maximum occurs about sunrise. The diurnal maximum takes place about 1 P.M., is less than double the minimum in miles per hour, and exceeds the mean of the day by about one-fifth only.—Average weekly temperature of thirty years (1846-75) at Cardington, by John Maclaren.—De la vulgarisation par la presse des Observations météorologiques, by M. Harold Tarry.

Physical Society, June 10.—Prof. G. C. Foster, president, in the chair.—Mr. W. J. Wilson exhibited and explained a reflecting tangent galvanometer which he has recently designed for the purpose of exhibiting the indications of the instrument to an audience, and so arranged that the divisions on the scale show without calculation the relative strengths of different currents. It should be observed at the outset that this object cannot be attained by attaching a mirror to the needle as in the ordinary galvanometer, as the angle passed over by the reflected ray is double that through which the needle is deflected. In the arrangement exhibited, the beam of light after passing through a small orifice traversed by cross wires, is reflected vertically by a fixed mirror: the ray then passes through a lens, and is again reflected from a small plane mirror parallel to the first, which is rigidly fixed below a small magnetic needle. By this means the ray becomes again horizontal, and, since the light now falls on the second mirror always at the same angle, the extent of motion of the ray is identical with that of the needle, and, if the scale be one of equal parts placed in the magnetic meridian, the indications on it will be proportional to the tangents of the angles, and therefore to the strengths of the currents. The needle and mirror are suspended by a silk fibre, and a bent strip of aluminium, the ends of which dip into water in an annular trough, is attached to the needle in order to check its oscillations. A series of observations taken with varying resistances introduced into the current, showed that the indications are very reliable.—Mr. S. P. Thompson then exhibited an electromotor clock made by Mr. W. Hepworth, of York, and provided with a commutator of Mr. Thompson's design. This part of the instrument is very simple, and reverses the current at each single oscillation by means of two light springs resting on inclined planes. The motion of the pendulum drives the train of wheels by a modification of the gravity-escapement, and a very small battery-power is sufficient.—Prof. G. Fuller, C.E., exhibited and described his "electric multiplier," an instrument which may be looked upon as an automatic electrophorus. An insulated plate of vulcanite is supported in a vertical position, and on each side of it is an insulated metallic plate, and these can be moved together to and from the vulcanite by rotating a handle. When these plates are far apart, two metallic arms provided with points are made to pass one on each side of the vulcanite plates. One of these is insulated, and is provided with a rod terminating in a knob, which at a certain point in its path almost touches the metallic plate on the opposite side of the sheet of vulcanite. The other arm is in connection with the earth. The action of the instrument is as follows. A charge of, say, negative electricity, having been given to the insulated arm, it is passed over its face of the vulcanite, while positive is drawn up from the earth and thrown upon the opposite face by the uninsulated series of points. These arms are then removed, and the two metallic plates are brought into contact with the vulcanite. Call the side of the plate charged with negative electricity A, and the other B. The negative of A induces positive on the near face of its metallic plate and repels the negative. This passes, by a strip of tin-foil joining the two faces of the vulcanite, to the other metallic plate neutralising its free positive, and when the plates are moved away from the vulcanite, that from A is charged with positive, and that from B with negative. Before reaching its extreme position this latter

communicates its charge to the insulated arm by the brass knob, the electricity is then distributed over the face A. At the ... of its path B is momentarily connected to earth. It will be evident that the effect of again bringing the plates in contact is to increase the charge of positive electricity on the metallic plate opposite the face A. With the small model exhibited, Prof. Fuller has frequently obtained sparks an inch in length.—Prof. Guthrie then exhibited and employed Prof. Mach's apparatus for sound reflexion, which is one of an interesting series of appliances designed by him for the demonstration of certain fundamental principles in physics. It consists of a mathematically elliptical tray, which is highly polished and provided with a close-fitting glass cover. The tray is covered with pulverised dry silicic acid, and a Leyden jar frequently discharged between two small knobs at one of the foci, when the silicic acid arranges itself in fine curves around the other focus.

Entomological Society, June 7.—Prof. Westwood, president, in the chair.—Messrs. A. A. Beiens, A. H. Swinton, and C. M. Wakefield were elected ordinary members.—Mr. Douglas made some further remarks on the "Corozo Nuts," known as "Vegetable Ivory," exhibited by him at the last meeting, which were attacked by a beetle of the genus Caryoborus. Mr. McLachlan, in connection with the above, exhibited the nuts of a species of Caryoborus (*C. bactris*) forwarded to him by Prof. Dyer. In this case each nut served as food for a single larva only, which bored in it a cylindrical hole of considerable size and depth; whereas the former nuts were infested with several larvæ in each nut.—The President exhibited the larva of an Australian species of Hepialus, from Queensland, bearing a singular fungus, with four or five branches issuing from the back of the neck and the tail; also a fungus growing out of the back of a Noctua pupa.—Mr. McLachlan, on behalf of Dr. Atherstone of South Africa, exhibited a couple of very singular Orthopterous insects (belonging to the Acrydiidæ), which in colour and in the granulated texture so exactly mimicked the sand of the district as to render it almost impossible to detect them when at rest. The insect was supposed to approach the *Trachyptera scutellaris*, Walker.—The President read descriptions and exhibited drawings of two very singular forms of Coleoptera from Mr. A. R. Wallace's private collection. For the first, which belonged to the Telephoridæ, he proposed the generic name Astychina, remarkable for the form of the terminal joints of the antennæ in one sex, which were modified with what appeared to be a prehensile apparatus, differing from anything known in the insect world, but of which some analogous forms were found to occur among certain Entomostracous Crustacea. The other pertained to the Cleridæ, and was named Anisophyllus, differing from all known beetles by the extremely elongated branch of the ninth joint of the antennæ.—Mr. Smith read descriptions of new species of Hymenopterous insects from New Zealand, collected by Mr. C. M. Wakefield.—Mr. J. S. Baly communicated descriptions of new genera and species of Halticinæ.—Dr. Sharp communicated descriptions of a new genus and some new species of Staphylinidæ from Mexico and Central America, collected by Mr. Salvin, Mr. Flohr, and Mr. Belt.—Part I. of the Transactions for 1876 were on the table.

PARIS

Academy of Sciences, June 19.—Vice-Admiral Paris in the chair.—The following papers were read:—Theorems relative to curves of any order and class, in which are considered couples of rectilinear segments having a constant product, by M. Chasles. Experimental critique on glycémia (continued), by M. Cl. Bernard. He illustrates these three points:—1. Sugar is rapidly destroyed in the blood after its extraction from the vessels. 2. Within the vessels, after death, sugar disappears rapidly. 3. In the living animal, the saccharine richness of the blood oscillates constantly.—On the cause of the movements in Crookes's radiometer, by M. Govi. He rejects the idea of an impulsive force of light, and of thermal currents of gas in the receiver; the causes he assigns being the dilatation by heat, or condensation by cold, of gaseous layers which all bodies retain at their surface, even in an absolute vacuum. It should be possible to obtain insensible radiometers, by heating the vanes, during the action of the mercury pump. M. Fizeau said the constant motion, for as long as an hour, of a radiometer placed in the centre of a circle of candles, was against this hypothesis.—Examination of new methods proposed for finding the position of a ship at sea, by M. Ledieu.—On the existence of mercury in the Cevennes, by M. Leymerie. In 1843 he had evidence that liquid mercury had been met with near a village at the foot of the Jurassic plateau of Larzac, was injurious to vegetation, was used to cure sheep disease, &c.—The plague in 1876; prophylactic measures, by M. Tholozan.—M. Pasteur presented a work entitled "Studies on Beer: its Maladies, and their Causes; Process for rendering it Unalterable, with a New Theory of Fermentation."—Influence of temperature on magnetisation, by M. Gaugain. Allevard steel and Sheffield steel undergo nearly the same *permanent* modification when subjected to the same alternations of temperature, but the *temporary* modification is much greater for the Sheffield steel than for the other. The coercive force is diminished by variations of temperature. The inductive action of a bobbin diminishes when the temperature increases.—Extension of the principle of Carnot to electric phenomena; general differential equations of the equilibrium of the movement of any reversible electric system, by M. Lippmann.—Letter to M. Dumas on experiments on the use of sulphide of carbon and sulphocarbonates, by M. Delachanal.—A letter from MM. Weyprecht and Wilczek was read, explaining their project for scientific exploration of the arctic regions.—Differential electro-actinometer, by M. Egoroff. Two of Edmond Becquerel's actinometers are arranged one above another in a common box, so that the current of the one is neutralised by that of the other, and a mirror galvanometer is interposed in the circuit. Each actinometer is a parallelopipedal box of glass with two opposite sides of hardened caoutchouc, and slits with silver plates in them. The outer box has slits to correspond, the width of which can be varied. The absorbing body to be studied is placed between the light and the slit corresponding to one of the actinometers, and the galvanometer noted when one and when both of the actinometers are in action.—Researches on the commercial analysis of raw sugars, by MM. Riche and Bardy.—On a new class of colouring matters, by M. Lauth. The first source of these has been the aromatic diamines obtained in reducing the nitrated derivative of acetylic combination of organic bases.—On some derivatives of isoxylene, by M. Gundelach.—On the spirophore, an apparatus for recovery of the asphyxiated, especially for drowning persons and new-born infants, by M. Woillez. (We notice this elsewhere.)—Graphic study of movements of the brain, by M. Salathé. Into an orifice of the cranium is inserted a glass tube, with caoutchouc stopper above, traversed by a smaller glass tube, which is connected with a lever and drum arrangement (of the Marey type). Water is poured in till it reaches about the middle of the small tube; its oscillations (from the brain surface) affect the registering lever. Among other results, the respiratory oscillations, observed simultaneously in the brain and the vertebral column, are synchronous. Artificial respiration reverses the order of oscillations, the liquid rising in inspiration, falling in expiration. Attitudes have a great influence. In efforts of any kind the oscillations are much increased.—Contractile vacuoles in the vegetable kingdom, by M. Maupas. The contractile vacuole has been regarded as a characteristic of animality. But various recent facts are against this. M. Maupas describes contractile vacuoles he has found in macrospores of the algæ, *Microspora floccosa*, Thuret, and *Ulothrix variabilis*, Kutzing (both in Algeria).—The mineral of nickel, in New Caledonia, or "Garnierite," by M. Garnier.—On nitrated alizarine, by M. Rosenstiehl

THE UNIVERSITY OF MANCHESTER

I.

WE have already alluded to a recent movement for procuring a University Charter for the Owens College, Manchester. While this took its origin in the teaching staff of the college, it has now, we believe, spread beyond these limits, and is at present engaging the earnest attention of the governing body of that institution. A pamphlet, drawn up by the members of the senate, and embodying their views, has likewise been sent to some of the most eminent men of the country, and replies have been received on the whole decidedly favourable to the object.

Under these circumstances we may be pardoned an attempt to discuss, however imperfectly, the present state of the higher education of this country, and to point out in what direction, and according to what principles, an improvement of the system may, in our opinion, most properly be brought about.

We shall therefore begin by a definition. Let it be understood that when we use the word University, we mean an institution in which, as far as training is concerned, the higher education of the whole man is contemplated. Now this means more than mere intellectual training—far more than mere intellectual instruction—for it means such a training as will turn out a man of high cultivation in all his powers—one able to take a leading part in the progress of his race. Such a cultivation has a four-fold aspect, moral, intellectual, social, physical. It may perhaps be giving undue prominence to this latter element, to insist upon the neighbourhood of a considerable river as a *sine quâ non* in founding a University, but this is only an extreme expression of the views entertained, we doubt not, by the authorities of Oxford and Cambridge, that a University should contemplate the physical training of its undergraduates, as well as what we call training in its higher forms. If these be the true functions of a University, it is almost superfluous to say that such an institution, in common with everything possessing vitality, must be constantly reforming itself, so as to adapt its training to the ever-varying and ever-advancing requirements of the age; and it is most certainly the part of a wise Government to consider how far the present institutions of our country meet its educational wants, and if they do not, to consider whether they cannot with propriety do something to supply these legitimate requirements.

Now this at once leads us to ask in the first place, What are the most distinguishing characteristics of the present age, or rather, perhaps, in order to limit our inquiry, of the British citizen of the age? what are, in fine, the essential conditions which the statesman must not ignore, but by which he must consent to be guided in all his attempts to legislate on the question?

In the first place, he cannot ignore what may be termed the religious difficulty. Perhaps, roughly speaking, about half the inhabitants of the country may be regarded as attached more or less to the Church of England, while the other half differ more or less widely from the tenets of that Church. Here it is evident that this difference of opinion does not imply any want of interest in religion, but the very reverse. What it does indicate is the line that must be pursued in all future legislation on the subject. The statesman must deal with men as they are, and in consequence of this difference he cannot afford, and indeed he will not attempt, to place the higher education of the country in the hands of one religious body, however powerful, whether this be the Church of England on the one hand or the positivists on the other. Such a policy may have been possible, perhaps even desirable, a couple of centuries ago, but it is neither possible nor desirable now.

In the next place, the statesman cannot ignore the fact that certain branches of knowledge and their applications have developed of late years in a very wonderful manner, so as almost to fix a new epoch in the progress of our race. The present is eminently the scientific age of the world.

Again this wonderful progress of scientific knowledge has added greatly to the wealth of the nation, especially in its larger centres of industry, and there is in consequence a very persistent and most praiseworthy cry for increased facilities for higher cultivation. Nor is this cry limited to scientific culture alone, in which case it would be less praiseworthy; but it embraces general cultivation, having, however, especial reference to these recently-developed branches of knowledge which have made our great cities what they are, and in which progress is necessary to a continuance of their well-being.

Now these inevitable conditions are not merely destined to regulate all future steps that may be taken for the spread of higher education, but they have already modified the position of the present institutions of our country, and besides this they are even now determining the action of Government in a variety of ways. The increased endowment of research, the loan collection of scientific instruments, and other developments which these will inevitably bring about, are indications that our present rulers are very much alive to the true welfare of the country. We are, however, here engaged rather with the future of the higher education, and we shall now show in what manner the principles we have dwelt upon have already modified our existing Universities.

To make this clear, let us begin by a brief description of the chief Universities of England and Scotland, and for this purpose we may confine ourselves to the two great English Universities, the four Scotch Universities, and the University of London.

The two great English Universities have come down to us from a time when the people of England practically thought alike on religious matters. Until recently these institutions bore all the marks of this ancient unity, inasmuch as they only gave their degrees and Fellowships to members of the Church of England. But it is well known that by recent enactments, not only degrees, but Fellowships may be held by those who are not members of the national Church. Nevertheless, while open to all, these Universities yet retain an especial relation to the Church of England, and we believe there is no widespread wish to see the connection violently altered.

In many respects these Universities are institutions

of great excellence, while in some respects they are altogether unique. In principle they embrace a very complete system of culture, in practice, however, it is found that their system is more especially adapted to the wealthier classes of the community. Judging of a tree by its fruits, we must not forget what a brilliant galaxy of statesmen, divines, philanthropists, and men of the highest general culture, have owed their training to these great Universities. It is when we come to strictly scientific professions, such as medicine and chemistry, that the deficiencies of these institutions begin to appear; neither Oxford nor Cambridge has turned out an appreciable number either of distinguished physicians or distinguished chemists. Those who are desirous to become proficient in these branches of knowledge almost invariably go elsewhere. The same may perhaps be said of the science of engineering.

It has been proved a great misfortune to the country that these two Universities have unwarrantably neglected the scientific training of their graduates. Nor is it untrue to say that in the past generation they have produced statesmen of unquestionable eminence, but yet profoundly ignorant of the scientific requirements of their country. It is only now, after a somewhat prolonged agitation, that the minds of the rulers of this country are becoming awake to the paramount value of science in the development of our resources.

Let us now briefly consider the four Universities of Scotland These institutions educate a far larger proportion of the people of Scotland than Oxford and Cambridge do of the English people. They are the training-schools rather of the middle than of the upper classes of the community. They excel in those branches in which Oxford and Cambridge are deficient, and they are deficient in those respects in which Oxford and Cambridge excel. Good medical men and men of good acquirements in various branches of science are produced by these Universities, but the accomplished scholar or mathematician is not produced—at least to any great extent. Nor, so far as we are aware, is any attention given to the physical training of the undergraduates. The Scotch Universities are not now connected with the Established Church of Scotland, except in the fact that there is a theological faculty attached to each of them, and that the Church of Scotland looks to that faculty alone for the theological training of its ministers. They are in the habit, however, of giving theological degrees with praiseworthy impartiality to eminent divines in all the somewhat numerous divisions of the Presbyterian Church, and occasionally to English Nonconformists.

The University of London is different from all these, inasmuch as it is entirely unconnected with any religious denomination. It had its origin, if we mistake not, in the wish to give degrees to those who, from adverse circumstances, had been unable to receive a University education, but who were yet possessed of the requisite information implied in a degree.

At the present moment a large number take advantage of this institution, and we believe that nearly 700 candidates presented themselves at the recent matriculation examination. Of these, however, the great majority are not unattached students, but are probably connected with some metropolitan or provincial college that has not the power of granting degrees. Thus the University of London is at present the degree-giving body for the alumni of a considerable number of colleges scattered throughout the country, and in virtue of this position it has a very great influence in regulating the studies at those institutions.

We have thus briefly described the present position of the higher education of this country, and it remains to consider in what respect the present system is deficient and how this deficiency may be remedied, consistently, of course, with those conditions which we have stated, and which no legislation can possibly ignore. This, however, must be reserved for a future occasion.

GALILEO AND THE ROMAN COURT

Galileo Galilei und die Römische Curie. Von Karl von Gebler. (Stuttgart, 1876. London: Trubner and Co)

THIS work supplies a continuous and detailed narrative of the circumstances under which Galileo incurred the hostility of the dominant party at Rome at the opening of the seventeenth century, and was by their influence denounced to, and ultimately tried and condemned by, the supreme tribunal of the Inquisition. An Appendix contains the text of the principal documents referred to in the body of the work. The whole forms a volume of rather more than 400 pages.

Such an undertaking, though it may, at first sight, appear a mere piece of surplusage to those who know how extensive is the already existing Galileo literature, is yet abundantly justified by recent events. Within the last ten years' original documents published in France and Italy, and German critical researches based upon them, have completely overthrown the view hitherto held by the most competent writers on this subject, and compelled the adoption of a diametrically opposite conclusion. All previous narratives of the trial of Galileo are thus necessarily superseded, and its history must be entirely re-written. Without attempting to explain the nature of the evidence which has brought about this change of view, a task much beyond my present limits, I propose to state wherein the change itself consists, and to what extent the opinions hitherto held concerning the conduct of the prisoner and of the Court are affected by it.

The essence of the charge against Galileo was, as we learn from the sentence finally pronounced, that after having been formally prohibited by the Inquisition from defending the Copernican theory, he had, in his Dialogues on the two rival systems of the universe, openly contravened this order, and so committed a clear act of contumacy, or, as we should call it, contempt of Court. On the question whether the accused had actually defended Copernicanism in his Dialogues, modern writers were able to form an independent judgment by the study of his incriminated work; but the statement about the injunction personally laid upon him by the Inquisition rested solely on the assertion of the Court itself, unsupported by one tittle of corroborative evidence. It is therefore a remarkable circumstance, and no bad illustration of how much may be done by strong asseveration, that the best historians, including some by no means antecedently inclined to repose a child-like confidence in the veracity of the Holy Office, one and all accepted its statement

on this decisive point as representing an undoubted historical fact. As Galileo's advocacy of Copernicanism was indisputable, the gratuitous admission of the second premiss of the Court necessarily also involved its conclusion, viz., that it had a right to punish the philosopher for his transgression of its command. Such accordingly was the practically unanimous verdict of historians.

Up to 1867 no portions of the proceedings in the case, except the sentence and form of recantation, had been made public in a trustworthy shape; but in that year M. de l'Epinois was permitted by the Roman authorities to publish *in extenso* the greater part of the original trial-record preserved in the archives of the Inquisition. A mass of fresh evidence thus became generally accessible, and was further increased by the publication in 1870, by Prof. Gherardi, of a second set of original documents bearing on the trial. It now became possible to check the statements of the tribunal by reference to the documents which it employed, and to the defence and depositions of the accused. This was done by Dr. Emil Wohlwill, of Hamburg, who, in a pamphlet published in 1870, showed that such a comparison led straight to the conclusion that the personal injunction asserted and relied on by the Inquisition had never been actually delivered to Galileo. Wohlwill supports this position by a mass of corroborative testimony extracted, with singular acuteness and ability, from Galileo's works and letters, and thus renders his case perfectly irresistible. These new results, striking and interesting as they obviously are, have attracted but little notice on the Continent, and an account of them given by me in a Friday evening lecture at the Royal Institution[1] constitutes, I believe, the only public attention they have received in this country.

As the charge advanced against Galileo was, after all, only formal and technical, his exoneration from it will hardly be considered as affecting in any considerable degree the estimate hitherto formed of his conduct in the matter, except indeed by those persons who consider unhesitating obedience to the will of a Roman Congregation as the duty of every right-thinking man. Unfortunately too, the nature of his answers under examination must influence opinion more considerably in an unfavourable direction. Not only did Galileo deny on oath having ever held the Copernican doctrine; he actually offered to write another Dialogue in refutation of the arguments in favour of the condemned tenet to be found in his former work, and protested his belief in the old Ptolemaic hypothesis as "most true and indubitable." Much allowance ought unquestionably to be made for an infirm and terror-stricken old man, but, even so, there remains an amount of really gratuitous insincerity on which it is painful to dwell, though it would be disingenuous to pass it over in silence.

As to the course pursued by the condemning tribunal, there can be little or no doubt that it deliberately lent itself to perhaps the most nefarious practice of which a judicial body can be guilty, namely, the admission of evidence known both to be false and to have been fabricated for the express purpose of securing a conviction which could not be compassed by fair means. The theological antagonists of the Holy Office have, no doubt, over and over again charged it with atrocities of this and of every other description, but I know of no instance save the present in which it has been convicted of such an enormity out of the mouth of its own records.

[1] On May 8, 1874.

Thus much of introduction appeared indispensable in order to define the point of view from which the volume in hand is written. Herr von Gebler regards the conclusions of Wohlwill as so firmly established, that his duty as an historian is no longer to discuss or defend them, but to weave them, together with the previously known facts of the case into a succinct narrative arranged in the order of time. Even to summarise the contents of his volume would be to attempt a fresh Life of Galileo. All that can be done here is to draw attention to a few of the salient incidents as they are presented in Von Gebler's pages.

It would seem that it was the Jesuits who, from beginning to end, were responsible for the persecution of the philosopher; and, most unfortunately for him, he quitted the service of the only State in Italy which could have enabled him to defy their machinations at the very time when its protection began to be urgently needed. Oppressed by the amount of lecturing and teaching incumbent upon him as Professor at Padua, and anxious, as it would seem, to illustrate in his own person the benefits to be derived from the "endowment of original research," Galileo applied for, and after some negotiation obtained, the post of first Mathematician about the person of the Grand Duke of Tuscany, which he hoped would secure him uninterrupted leisure for the prosecution of investigation and discovery. Von Gebler comments as follows on this calamitous step:—

"In spite of all the great advantages which this new post brought him, Galileo made a thoroughly bad exchange when he quitted the free territory of the Venetian republic in order to commit himself to the doubtful protection of a sovereign who, though personally very well disposed towards him, was young, vacillating, and, moreover, completely under the control of Rome. It was essentially the first step in the course which led Galileo towards his doom. Complete freedom of teaching existed actually in the Venetian Republic; nominally only in Tuscany. In Venice politics and science appeared guaranteed against Jesuit intrigues, for when Paul V. had thought fit to lay the uncompliant Republic under an Interdict (April 13, 1606), the Fathers of the Society of Jesus had to submit to immediate and permanent expulsion from its territory. In Tuscany, on the other hand, where the Order was thoroughly at home, its mighty influence lay heavy on all that touched its interests, and especially therefore on politics and science. Had Galileo never forsaken the fresh healthy air of the Free State, in order to breathe a close Rome-infected Court atmosphere, he would, there is every reason to believe, have escaped the subsequent persecutions of Rome, inasmuch as that same republic which, but shortly before, had not allowed itself to be intimidated by the papal excommunication pronounced against its Doge, its Senate, and its entire Government, would assuredly not have delivered up one of its University professors to the vengeance of the Roman Inquisition."

The period of private controversy during which the question at issue between the old and the new astronomy was forced, against the wish of Galileo, from a scientific to a theological mode of discussion, is very fully described by our author, who gives many amusing instances of the

ludicrous manner in which the Aristotelian philosophers attempted by *à priori* logical considerations to disprove the reality of the celestial appearances revealed by the telescope, and "as by magical enchantments to conjure them out of the heavens." So far as the *truth* of the Copernican theory was concerned, these individual skirmishes were put an end to by the peremptory decree of the Index Congregation (March 5, 1616), which reduced the revolutionary theory, for all Roman Catholic astronomers, to the level of a mere hypothesis, convenient indeed for the representation of phenomena, but not corresponding to actual external facts. This, the undoubted scope of the decree, which has escaped most previous writers, is carefully stated by von Gebler. The point is one of much interest, since the repressive attitude then taken up was not finally abandoned until as late as 1820. Two hundred years of astronomical research were needed to break down the unyielding Papal *non possumus*.

The appearance in 1632 of Galileo's Dialogue on the Ptolemaic and Copernican systems was the signal for the final catastrophe. Its high significance is well brought out in the following extract:—

"The book contains far more than the title promises, for the writer has, in connection with his discussion of the two great systems of the universe, introduced a record of almost every important result obtained by him during nearly fifty years of scientific research and discovery. The author shows himself determined to adopt a style which should appear not exclusively calculated for scholars, but, on the contrary, intelligible and even highly attractive for every really educated man. The essential object of the book was to spread abroad as widely as possible a clear recognition of the constitution of nature in its absolute and final form. That this object was so successfully achieved is attributable not merely to Galileo's philosophic, but, in the first instance at least, perhaps even more to his literary eminence. The external form of the work was in itself most happily chosen. There is not a trace of the dryness of a systematic treatise in which proof succeeds proof with a wearisome monotony, hardly relieved by a single pause. On the contrary, the facile lively form of dialogue so tolerant of digression, gave the author full opportunity to develop his impetuous eloquence, his singular power of reasoning, his biting satire—in short, his special and brilliant style."

Next let us observe the effect of the work on the enemies of its author:—

"Galileo, as one of the most momentously effective of pioneers, was in a high degree obnoxious to the Jesuits, and members of the order had repeatedly been signally worsted in scientific conflicts with the great philosopher, a circumstance by no means fitted to dispose the Fathers of the Society more favourably towards him. As soon as they recognised that in his latest work he had employed an immense array of facts and an overwhelming force of argument for the destruction of the fundamental principles of the old school, in order to build up with an inexorable logic the modern edifice upon its ruins, the Jesuits set all their levers to work to secure the suspension of the revolutionary book, and later, to bring about the ruin of its dangerous author. A prosecution before the Inquisition was their most convenient, indeed probably their only possible weapon."

The notion, still entertained by some writers, that nothing really serious was meant by the trial, but only the settlement of a point of ecclesiastical etiquette, is totally dispelled by the evidence stated in von Gebler's narrative. We see Galileo completely panic-stricken on first receiving the summons of the terrible tribunal, endeavouring in every possible way to keep out of its grip, and only finally complying when the Court had actually issued its writ to have him brought up to Rome *in irons*. We see the Grand Duke of Tuscany writing autograph letters to the Cardinals who were members of the Holy Office, begging for a favourable consideration of his servant's case. We see the Pope himself in a fit of ungovernable fury against Galileo;—fury so intense that the Florentine Ambassador, who had provoked it by defending the philosopher, precipitately dropped the subject, "lest he too should be charged with heresy by the Holy Office." During the slow progress of his case in Rome, Galileo was unquestionably treated with quite exceptional favour, in being allowed to reside in the house of the Ambassador except during the days of his actual examination, and even then lodged in comfortable rooms in the apartments of the Commissary Fiscal, instead of in the ordinary prison. Of what took place during the examination we are not completely informed. That the prisoner was threatened with the torture is certain; whether it was actually inflicted is still a moot point. Von Gebler very confidently maintains that it was not, and his reasoning at least proves that, if employed at all, it must have been but slightly.

The closing portion of the narrative presents a dismal picture of years lingered out amid severe physical suffering under the stony-hearted supervision, constant petty interference, and reiterated threats of the Holy Office. And when at last the old man dies, blind and helpless, but surrounded with a glory destined to outlive that of popes and cardinals, the Inquisition is seen nervously bustling about to prevent any memorial being erected to the great astronomer, "lest the good be scandalised," or if that could not be achieved, at least to secure that neither in the inscription nor in the oration pronounced at the grave, "words should occur injurious to the reputation of this tribunal."

"The feeble Duke of Tuscany did not venture to disregard in the smallest degree these unamiable Papal wishes. Even the last directions of Galileo, that he should be laid in the tomb of his ancestors in the church of Santa Croce at Florence, were not respected. The insignificant side chapel of that church, called the *capella del novisiato*, received the mortal remains of the great departed. His body was there buried quietly and without public ceremonial in accordance with the will of Urban VIII. No memorial, no inscription marked his last resting-place. But, do what Rome would to wipe out the memory of the famous philosopher, she failed in her attempt to bury in the same grave with his lifeless corpse, the immortal name of Galileo Galilei."

Herr von Gebler has performed his task with meritorious zeal and conscientious labour. He is scrupulously accurate in his use of authorities, and shows a fixed determination—no small merit in a biographer of Galileo—not to exchange the standing-ground of history for the quicksands of ecclesiastical controversy. His narrative is clear and readable, though not free from a tendency to diffuseness and verbal redundancy which are more sharply criticised in England than in Germany. On one point only does he appear to me open to any serious censure,

viz., in the amount of recognition which he has assigned to the principal pioneer in the department of history on which he writes, I mean, of course, Dr. Wohlwill. Without wishing to imply that von Gebler has intentionally minimized the credit he has given to Wohlwill, I certainly think that a person acquainted with the latter's pamphlet only by the former's references, would form an inadequate conception of the extent to which its few and unassuming pages have supplied both materials and suggestions since incorporated and turned to account in the present work.

SEDLEY TAYLOR

MARGARY'S JOURNALS AND LETTERS

The Journey of Augustus Raymond Margary from Shanghae to Bhamô, and back to Manwyne. From his Journals and Letters. With a brief Biographical Preface, and concluding Chapter, by Sir Rutherford Alcock, K.C.B. Portrait and Map. (London: Macmillan and Co., 1876.)

THE publication of these journals and letters can only serve to confirm and deepen the general regret felt at the untimely fate of Mr. Margary. After looking at the manly, genial, and determined face which Jeens has so faithfully reproduced, and reading the hurried but able and invariably interesting notes which have been preserved of the now famous journey, one burns with vexation that through some possibly preventible misunderstanding or ignorant blunder, so promising and noble a youth should have been sacrificed, just when he had shown of how great things he was capable. We need not here enter into details with which, doubtless, all our readers are familiar through the daily press, and to which we have already referred in connection with Dr. Anderson's recent work (vol. xiii., p. 422), to which the present publication is the fitting complement.

The Indian Government had determined to make another attempt—Sladen's in 1868 was a failure—to open up a trade route between Burmah and China. A party was to leave Bhamô in January, 1875, cross the frontier, and make its way to Shanghae. It was thought advisable that some one should traverse the route in an opposite direction, so as to meet this party on the frontier; Mr. Margary, who had been for some years in our Consular Chinese Service as interpreter, was selected for the critical but honourable duty, and in accordance with instructions set out from Shanghae in August, 1874. The energetic youth—he was twenty-eight years of age—eager to be of use in the world, and naturally eager for distinction, rejoiced to have such a splendid opportunity, dangerous though he knew the task to be, and with speed and secrecy made his preparations, and set out furnished with a pass from the Chinese Government. He had a journey before him of not far short of 2,000 miles, right through the heart of the Chinese Empire, a large portion of the distance over ground not previously traversed by any European. About one half of the distance was in steamer and by boat up the Yang-tse-Kiang, and its tributary, the Yuan. At Chen-Yuan-Fu, in the Kwei Chou province, he was furnished with carriers and baggage animals, and thus safely made his way to his destination, Bhamô, in Burmah, a short distance on the other side of the Chinese frontier. Probably no one ever made a journey of such length through any part of China and met with fewer obstructions. It was not the pass he was provided with that alone did it, for in one or two instances the officials of towns could annoy him in spite of it. It was his humanity, his toleration, his geniality and sense of humour and disposition to see the best side of everything and everybody; it was these qualities combined with his perfect acquaintance with the language and knowledge of and respect for Chinese customs, along with a determination to make his mission a success, that carried him safely and happily through circumstances in which ninety-nine others would have come to grief.

During a great part of his journey, Mr. Margary was almost prostrated by illnesses of various kinds; yet those are mistaken who think that the book before us contains merely a few meagre scraps thrown together to make up a volume. In spite of illnesses and of the fact that as in duty bound he made all haste to get to the end of his journey, Mr. Margary contrived, by observation and intercourse, to obtain a substantial amount of really valuable information about the country and the people through which he passed. He had of course no time for minute exploration, though a fair acquaintance with geology and botany qualified him for profitable work of this kind; but his journals and letters contain many important notes on the physical geography and resources of the extensive tract through which his journey lay. He kept eyes and ears open, and his notes show that in this part of China there is plenty of scope for mining and commercial enterprise, and a fruitful field awaiting the scientific explorer. Many important observations will also be found in these remains concerning the people of the various districts and their ethnological relations. Especially do the notes of his intercourse with officials, and non-officials as well, serve to shed a light on Chinese character that we are sure will be new to many. Mr. Margary set himself from the first to understand the Chinese, a task of the greatest difficulty, and came to the conclusion that the common notions on this curious people are far from correct.

The brief biographical sketch and a few early letters enable one to trace the growth and training of the unfortunate youth from his school-days. He was evidently made of excellent stuff to begin with, and took the best possible advantage of his educational opportunities. When only about twenty he was appointed as interpreter to China. Here he speedily acquired a mastery of the language, and did duty at various places before his last settlement at Shanghae. While on the island of Formosa he supplemented his defective scientific education by, as we have said, the acquisition of a knowledge of botany and zoology. On several occasions, moreover, before his final feat, he showed his readiness of resource, bravery, determination, and skill in dealing with men. And yet, through some yet unexplained blunder, this splendid young fellow, so well adapted for long service to his country and to science, was obscurely and brutally murdered in a petty Chinese village. The mission under Col. Browne had proceeded on its way some little distance beyond the Burman frontier, when Margary volunteered to go forward with one or two attendants to remove some seemingly small obstruction at Manwyne. No more was

seen of him alive by his party; his murder at Manwyne was evidently part of a scheme to attack and murder the whole party, who of course returned frustrated in their object.

It is not for us to enter into any discussion as to who are the real authors of the treacherous affair, so far as data permit, Sir Rutherford Alcock discusses the whole question, as well as shows the value of Margary and of his journey, in an Appendix. Whoever was to blame, Margary himself was blameless. it is difficult to regard his death as anything but an unrelieved loss. we trust her Majesty's Consular Service contains many like him.

OUR BOOK SHELF

Through Bosnia and the Herzegovina on Foot during the Insurrection, August and September, 1875. By Arthur J. Evans, B.A., F.S.A. With a Map and 58 Illustrations. (London: Longmans and Co., 1876.)

THIS is an opportune publication, and we recommend it to our readers as one that will give them a good and lively idea of the countries referred to and their various peoples—of much interest at present in connection with the Servian rising. Mr. Evans entered Bosnia at Brod on the Save, went leisurely south, with various divergences, through the country, reaching the sea near the mouth of the Narenta and coasting along to Ragusa. Mr. Evans mixed freely with all classes of the people wherever he went, is well acquainted with Bosnian, and indeed with general European history, is a discriminating ethnologist, and has a good knowledge of botany. He studied the features and habits of the people closely as he sojourned among them, and gives many notes that might be found of value to those who take interest both in Aryan and Turanian ethnology. The people are evidently capable of good things if they had the chance and were free from oppression; but Mr. Evans's observation confirms all that has been said as to the impossibility of the Turk ever treating a Christian subject with justice or even humanity, unless compelled. The book contains a map and many attractive illustrations, is interestingly written, and will give English readers a fair idea of a country that is almost as little known to the generality as the heart of Africa.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Firths, Dales, and Lakes, Valleys and Cañons

IN NATURE, vol. xiii. p. 481, you honoured me by printing a notice of some writings on glacial subjects, and since then many pamphlets have been sent to me. I would gladly show that I have studied them. Though I do not believe in a "glacial period," I have convinced myself that local glacial climates, like the existing climate of Greenland and the "Arctic current" have prevailed in different regions at different times, and that marks of these "local glacial periods" include "valleys" of certain forms, with "firths" and "lake basins." Glaciation occupied the attention of the Geological Society at their last meeting, when Prof. Ramsay read an abstract of a paper, in which a foreign writer compared Greenland and Norway. So far as I understand that writer's views as to glacial action in general, I agree with him. Many writers hold opposite opinions as to "the usual evidence of powerful ice erosion," and "the alleged power of a glacier to excavate a depression in the earth's surface" (Judd), as to "abrasion," and "the inability of glaciers to excavate except under peculiarly favourable circumstances" (Bonney). Truth is learned by observation and by perseverance. A drop hollows a stone, not by force, but by frequent falling, and that truth has become proverbial. A stream of water by flowing, and by rolling stones, makes a watercourse, and that truth is proved by every shower and in every gutter. By perseverance flowing water makes a deep watercourse. According to the latest official report of Dr. Hayden (June 4, 1876), streams which began to flow about the sources of the Mississippi, when the Rocky Mountains were raised, have gone on flowing ever since in the same channels, and some have worn cañons "from half a mile to a mile deep," not by force, but by frequent flowing. A glacier also flows. It is acknowledged that it wears and grooves rock, but still it is denied that a wide deep stream of flowing ice can make a wide deep furrow. It is said that ice "abrades," but does not "erode," that it cannot "excavate," unless under favourable circumstances. It is maintained that flowing ice cannot hollow out a basin, though flowing water does it on a small scale wherever it flows. Much is done by perseverance. As a drop hollows a stone, and water a watercourse, so ice makes an ice channel slowly, and much repetition by glacialists may in time convince sceptics of that truth. Icebergs are the ends of glaciers pushed out into the sea, and there launched. Some of them are 3,000 feet thick. They prove their size by grounding in soundings off Newfoundland, and Labrador, and Greenland, and by their rate of flotation when they float with 300 feet above water, as "flat topped islands of ice" in southern seas. A "glacier" cannot easily be measured on shore, but these vagrant fragments roughly measure parent glaciers. A pressure of 3,000, or of 1,000, or of 500 feet of ice upon sand or stone moving in an ice-channel is great abrading force. At the base of every ice fall, or ice rapid, the plunging ice river must tend to "excavate," because falls and rapids of water excavate pools of various sizes proportioned to their power. The area of Greenland nearly equals that of India, and that area, so far as it is known, is covered with thick ice which is slowly moving seawards. The coasts are furrowed by deep hollows, of which most contain flowing glaciers, of which many enter the sea, and launch "islands of ice." Some "bergs" now float to the lowest latitude reached by northern drift stones on shore in Europe and in America. I say nothing here about marine glaciation. The Greenland glaciers are flowing from an area where water generally falls frozen; they flow as rivers now flow from India, and all of them are slowly wearing their channels at some rate, and working up stream like Niagara Falls. There is no measure for the time during which these powerful ice rivers of Greenland have been slowly hollowing stone by frequent flowing, unless it be the work of erosion done. It is denied that the work was done by the glaciers. Yet no rivers flow where ice fills the dales, and these Greenland dales have been "eroded," and bear "the usual evidence of powerful ice erosion," according to photography and descriptions. According to the clearest marks the whole Scandinavian peninsula, and the whole of Finland have at some time been covered by ice on the scale of Greenland ice. Sermitsialik glacier, photographed by Mr. Bradford before 1870, is near Cape Desolation in Greenland, opposite to Shetland, Bergen, Christiania, St. Petersburg, &c. It is from three and a half to four miles wide where it enters the sea, and there it is about 800 feet thick. It extends inland as far as the eye can reach, and probably comes from the watershed of Greenland. Taking the ice to weigh only 55 lbs. per foot cube, the pressure above the sea level on the ice channel is about 44,000 lbs. on the foot square. Between ice and rock are huge stones, grit, and mud, and the rock is rounded where it is visible at the edge of the glacier, near the sea-level. The slopes between the lakes of Finland, and the gulf near Viborg, at the side of the Saimen canal, and elsewhere, are polished, striated, and rounded. I took rubbings in September, 1865, and recognised the work of ice on the scale of Greenland ice. In Norway the old marks are plain on the sides of firths and dales, and some lead back to glaciers, which still flow from large areas upon the watershed, which still are covered by considerable sheets of ice. In Greenland this engine is seen at work, in Scandinavia the work of the engine is better seen. That work is, first a rounded worn plateau about the watershed called the "fjeld," second, a series of slopes much glaciated, and third, below these slopes, long grooves hollowed out of the solid, called "dales." In these dales rivers now flow to lakes and to firths. Of these rivers some have worn deep watercourses, and cañons proportioned to their size and age. At the bottom of the dales are hollows which are called lakes, and firths when they hold fresh or salt water, in the rivers are smaller

pools, which become ponds in dry weather. This northern country opposite to Greenland has been "carved" in this fashion by ice on the large scale, and afterwards by water-streams, and by the frequent falling of rain drops. It has also risen from the sea. The ice-cover has been taken off Scandinavia and Finland, and there it is possible to test theories about the work which an ice-cover is now doing on the present chief gathering grounds of snow throughout the world. But that Scandinavian work is the same kind of work which is found with small glacial marks elsewhere. Hollows have rounded sections ⌣, or when deep they are like U. Hills between hollows commonly are hog-backs ⌢, and generally the land is rounded, except where peaks rise, and cliffs have broken. But this kind of rounded sculpture exists only in some regions of the world, and it marks the site of local glacial periods, as I believe. Elsewhere the section of valleys is angular like V, or in cañon countries like Y. These angular grooves are known to be the work of streams, because every stream of water carves on the same plan. Rounded hills and dales are at first sight evidence of powerful ice erosion, but some kinds of rock weather in bosses. If it be admitted that a drop wears a stone, that a stream makes a deep cañon in a long time, and that a glacier "abrades" or makes any mark at all, it seems to follow that an ice-engine as large as India or Scandinavia has in fact done the large work which it might be expected to do by perseverance in working, as it is known to work, wherever snow now gathers in large masses. Given the hardly perceptible wearing of water and time, a cañon a mile deep and many hundreds of miles long has resulted from the flowing of a stream. Given glacial "abrasion" and time enough, than valleys of rounded section, and firths and lake-basins of a particular kind probably resulted from the flowing of ice.

There are plenty of hollows in the earth's surface which are not the result of erosion but of other causes with which I am not now concerned. Where a stream flows from source to mouth on a gradual slope, there has been no great disturbance of level since the stream began to work. Where ice fills the dales there are no cañons. Where ice has filled dales and has left fresh marks, cañons are short and small. In mountain regions where ice-marks are rare or absent, cañons are of great depth and length, apparently because their streams have flowed in the same channels ever since the mountains were raised. But where cañons are marked features, these lakes, firths, and dales of rounded section are very rare, or do not exist. It seems therefore that hollows which have, in fact, been carved out of the earth's surface may be known for water-work, or for ice-work by their shape, and that firths, dales, and lakes may mark the sites of local glacial periods; and cañons the sites of climates that have not been glacial since the streams began to flow. Perseverance may accomplish great results insensibly like ice in dales, water in water-courses, and drops on stone.

Let me counsel those who wish to study the works of ice on a large scale to abandon the retiring glaciers of Switzerland and study Nature in Norway. This is the best season for travelling there. J. C.

June 23

The Loan Scientific Collection at South Kensington

As a science teacher, privileged to attend the special demonstrations upon the extraordinary assemblage of apparatus now filling the galleries of the exhibition buildings, a list of some of which appeared in last week's NATURE, would you allow me to call attention to the provision of the department by which the general public may be admitted, if room, at a nominal charge.

Within the past few days my note-book shows that the original instruments of Sir Isaac Newton, Faraday, Fizeau, Wheatstone, Watt, Savery, Black, Cavendish, Guericke, and others employed in their classic researches, have been shown and explained (and used, so far as experimentalists would presume to touch such now almost venerated relics).

The spacious and well-appointed lecture-theatre has not been always crowded; but I have the impression that if the above regulation were widely understood there would be such a gathering, not of the merely curious, who would attend as at an entertainment in natural magic, but of those deeply interested in the topics discussed, as would prove too large for the accommodation at present provided; and, whilst scientific enrichment of the public would be more largely secured, a compliment would at the same time be paid to the directors for their great efforts to promote the success of this important undertaking.

The School of Science, July 6 WILLIAM GEE

Evolution of Oxygen by "Vallisneria Spiralis"

HAVE any of your readers noticed the rapid evolution of oxygen by a blade of *Vallisneria spiralis*? If a blade is cut or broken and held under water, the bubbles of gas are rapidly noticed issuing from the broken end, and by a simple arrangement of placing the broken blade or several blades into a test tube filled with water the water is displaced and the gas collected. After forty-eight hours the pores of the broken end of the blade close up and a fresh fracture is necessary to restore the evolution of gas, which also ceases at night only to recommence when the sunlight reappears. I have collected about a cubic inch of gas in eight hours from one blade of the plant. A confirmation of my experiment would please me.

Stroud, July 3 WALTER J. STANTON

Stamens of Kalmia

IF the beautiful spring trap formed by the stamens of the Kalmia, by which insect fertilisation is secured, has not yet been noticed, I may perhaps be allowed to call attention to it.

Cahirmoyle, Ardagh, Co. Limerick C. G. O'BRIEN

Optical Phenomenon

FOR more than half an hour after sunset this evening there was a broad band of light rising vertically through a clear sky immediately above where the sun had set. It moved as the sun moved northward below the horizon, retaining its vertical position. It must have been formed at a very great height in the atmosphere, for it outlasted all the other sunset tints, which were very beautiful. It would be interesting to know whether this was seen from many places far apart. JOSEPH JOHN MURPHY

Old Forge, Dunmurry, Co. Antrim, June 27

The Cuckoo

WITH regard to the letter of Mr. Adair, in last week's NATURE, p. 210, on the cuckoo, I have only to observe that if it does not sing in Somersetshire after Midsummer it does *here*, in Middlesex; I heard it, to my astonishment, early in the morning of the 6th inst., in the woods and hills to the north. I never recollect its note so late, not after the 3rd.

Harrow, July 10 HENRY ST. JOHN JOYNER

OUR ASTRONOMICAL COLUMN

SHORT'S OBSERVATION OF A SUPPOSED SATELLITE OF VENUS.—This observation which, as it appears in the *Philosophical Transactions*, vol. xli. (NATURE, vol. xiv., p. 194), is mystified by a typographical error, is also found in "Histoire de l'Academie des Sciences, 1741," p. 125, where the micrometrically-measured distance of the suspicious object from Venus is given in what seems to be a more correct form, and as it was used by Lambert in his calculations. After referring to the observations of the elder Cassini in 1672 and 1686, the writer—probably Cassini II., author of "Elemens d'Astronomie"—states that Mr. Short had again seen the satellite, real or apparent, in the preceding year (1740), under similar circumstances, and with the same phase as Cassini had described; he had been informed of this in January, 1741, by M. Coste, "auteur de la Traduction du livre de l'Entendement Humain de Locke, et de plusieurs autres ouvrages;' and having communicated the observation to the Academy of Sciences, had been charged by that body to inquire more particularly concerning it, and report the result. But as Short had not seen the satellite again up to June, 1741, nothing further was ascertained than had been notified in the letter addressed to M. Coste, which was from "Mr. Turner, written from London, June 8."

Short's observation was "made in London, November 3, 1740, in the morning, with a reflecting telescope of 16½ English inches, and which magnified the diameter of the object from fifty to sixty times. He perceived at first what appeared to be a small star very near to Venus, upon which, having applied to his telescope a stronger eyepiece and a micrometer, he found the distance of the

small star from Venus, 10 minutes 20 seconds. Venus then appeared very distinctly, and the sky being very clear, he took eyepieces three or four times more powerful, and saw, with an agreeable surprise, that the small star showed a phase, and the same phase as Venus; its diameter was rather less than a third of that of Venus, its light not so vivid but well defined; the great circle which passed through the centres of Venus and of the satellite, which it would be difficult to designate otherwise, made an angle of about 18 to 20 degrees with the equator, the satellite being a little towards the north, and preceding Venus in right ascension. Mr. Short examined it at different times and with different telescopes during the space of an hour, until the light of day or of the twilight obliterated it entirely."

It will be seen that Short's observation, divested of the typographical error in the *Phil. Trans.*, by which it was confused, is intelligible enough, and it may not be without interest if we examine the circumstances under which it must have been made.

Taking the place of Venus with sufficient precision for the purpose in view from the tables of Le Verrier, we have the following figures:—It may be premised that the date given in NATURE last week from the *Phil. Trans.* is the morning of October 23, but it is to be remembered that the Gregorian style had not then been introduced in this country; in the present mode of reckoning, it becomes the morning of November 3, as stated in the "Histoire de l'Académie."

G M T	Venus, App R A	App. N P D.	Dist of Venus from the Earth
1740, Nov. 2, at $18^h\ 30^m$	175° 21′ 11″	87° 12′ 21″	0·7007.

Hourly motion in R.A. + 2′ 28″; in N.P.D + 0′ 49″.

The apparent diameter of Venus (Le Verrier) was 23″·7, and her heliocentric longitude being 86° 11′, and her geocentric longitude 174° 38′; the breadth of the illuminated portion of her disc was 0·514; elongation, W. 46½°.

Short says the daylight put a stop to his observations "about a quarter of an hour after eight," which we may assume to imply apparent time, and as the correction from apparent to mean time was then $16^m \cdot 1$ subtractive, his observation may be supposed to have terminated at 8 A.M., and as he had viewed the object during the space of an hour, we find Venus must have been at an altitude of 36° when he first perceived it, and further, it should be noted, the sun rose at $7^h\ 0^m$, so that Short's observations must have been made entirely in daylight, with the planet particularly well situated.

The suspected satellite was 18°-20° north-preceding Venus, which implies a mean angle of position of 289°, and as the distance was 10′ 20″, we have for the difference of right ascension, $39^s \cdot 1$, and for the difference of N.P.D., 3′ 22″. Supposing these differences to apply to $7^h\ 30^m$ A.M., the position of the object would be R.A. $11^h\ 40^m\ 50^s \cdot 6$, N.P.D. 87° 9′ 23″; whence, bringing forward to the epoch of the *Durchmusterung*, its R.A. is $11^h\ 46^m\ 46^s$, N.P.D. 87° 47′·5 for 1855·0.

Unless we had been able to correct the misprint in the *Phil. Trans.* by the French account of the observation, it might, perhaps, have been inferred that the distance was intended to be 1° 2′ or 1° 12′, and in this case the 3·4 magnitude star β Virginis would have fallen very nearly upon Short's position; at 7 A.M. this star preceded Venus 1° 5′, and was N. 26′.

It will be found that our examination of Short's observation does not tend to explain it. Though Lalande thought when conversing with him on the subject in 1763, that he doubted his having observed a satellite of Venus, he appears to have been sufficiently impressed with his observation to have had the appearance engraved, and to have "carried it with him as a seal."

The observation of Andreas Mayer at Greifswald, mentioned in NATURE last week in the notice of Schorr's "Der Venusmond," was communicated to Lambert after the appearance of his memoir "Essai d'une théorie du satellite de Vénus," in the Berlin Memoirs, 1773, of which an abstract is found in the *Astronomisches Jahrbuch*, 1777. It is printed at p. 186 of the *Jahrbuch* for 1778, where also appear the two letters from Abraham Scheuten to Lambert, referring to his observations of what he believed to be a satellite of Venus, *after* the planet had left the sun's disc in the transit of 1761, June 6, which at noon at Crefeld was near the centre of the disc and at 3 P.M., near the limb. Lambert follows with a particular examination of Scheuten's observation in connection with the observations of Montaigne at Limoges in May preceding.

γ ARGUS.—Gilliss, in the notes to the 1850 "Catalogue of Double Stars observed at Santiago," remarks of this object: "The cluster deserves special attention for its evident changes since Herschel's observations." From a comparison of the observations it is not obvious to what changes reference is here made. Perhaps some reader of NATURE who can favourably command this star's position will describe the actual configuration, &c., of the principal star and *vicinæ*.

Mr. S. M. Drach writes with reference to views of binary stars from Venus and Mars: "Has it ever been noticed by cosmographists that an observer at these planets must see our moon at a maximum elongation-angle from our earth, ranging from Venus from $5\frac{1}{11}$ to $31\frac{1}{7}$ minutes of degree, and from Mars from $3\frac{1}{3}$ to $16\frac{5}{6}$ minutes of degree, whence follows that our *present century's* certitude of Binary Stellar Systems is a PRIMITIVE feature of naked-eye astronomy to the Venus or Mars observers. This elongation diminishes to zero in about seven days of either planet, since their rotation periods nearly equal the earth's."

THE NORWEGIAN-ATLANTIC EXPEDITION

THIS Expedition left Bergen June 1 for the Sognefiord, where the first week was spent in preparatory work—sounding, dredging, and trawling in 600 fathoms. The temperature at the bottom was found exactly the same as in former years, 43°·7 F. The fauna was a mixture of Atlantic and Arctic. There were found several specimens of *Brisinga coronata* (Sars), *Munida tenuimana*, one large *Actinia* and a sponge, *Tisiphonia agariciformis*, and, among other mollusca, *Axinus eumyarius* (Sars), *Kelliella abyssicola* (Sars), *Malletia obtusa*, and *Taranis Mörchi*. The second week was spent at Huso, a small island at the mouth of the Sognefiord, where magnetical base-observations were made on shore and on board, ship swung for deviation, &c.

June 20 the Expedition left this place, and steered along the deep channel surrounding Southern Norway from the Skagerrack up to Cape Stadt. The first soundings and dredgings showed a very flat bottom at a depth of about 200 fathoms, and with a fauna mainly Atlantic. About 150 miles N.W. of Cape Stadt the temperature began to fall, the depth remaining unchanged. At the next sounding the depth increased and the bottom temperature was still falling, until at last the Miller-Casella thermometer showed 32° at 300 fathoms, and 30° at the bottom in 400 fathoms. This is exactly like what the *Porcupine* found in the *Lightning* Channel. Off Stadt the fauna was Arctic and Glacial. Among the specimens brought up was a gigantic *Umbellularia*, 5 feet high, a *Nymphon*, 10 inches between the ends of the feet, a new large *Archaster*, and many other characteristic forms. No less than eight forms of Hydroids were also found at this depth, three different species of Arctic *Fusus*, and several specimens of *Yoldia intermedia*, &c.

The Expedition ran into Christiansund June 23, and was to leave that port in a few days for the Faroes and Iceland.

THE KINEMATICS OF MACHINERY[1]

II.

AFTER the discussion of lower pairs of elements, higher pairs are considered, such, for instance, as that of the duangle and triangle, the motions of which with respect to each other are thoroughly described. One of the most useful sections of the book, and which we strongly recommend to the attention of engineers and machinists, is that on the General Determination of Profiles of Elements for a given Motion (p. 146). To the practical mechanic who has read the discussion on the different pairs of elements, it must appear that there are some motions taking place in machines in the required manner that are not constrained completely by the resistance of the parts of the machine, such, for example, as the motion of the bed-plate of a planing machine in the V guides, and it is obvious that this motion would not be constrained to take place in the required manner if the machine were turned upside down. The constraint only in certain positions of the pair of elements is called *force closure*, and the pair is called an incomplete pair of elements, the determination of the motion in the required manner being effected only with the assistance of the weight of one element, which must be greater than any disturbing force tending to cause motion in the direction opposite to that in which its weight acts. As examples of force-closed pairs are mentioned the plummer block of a water-wheel, which, owing to the weight of the wheel, constrains the motion without the complete closure of the pair by the addition of the cap, also railway wheels with the metals on which they roll.

We pass now to the History of Machine Development. "At the commencement of a study of machine development it is first of all necessary to know distinctly what it is that makes a machine complete or incomplete. It is only possible to judge of the completeness of a machine from the excellence of the work produced by it, if we are able to estimate separately what part of the result is due to the skill of the workman. Certain Indian fabrics, for instance, are of extraordinary excellence and delicacy, although they have been made in most defective looms; throughout the whole manufacture of these it is the weaver's dexterity that plays the most important part. In no machines can we absolutely do away with human action, if it be for no further purpose than to start and stop the process. It appears, therefore, that the most complete machine is the one fulfilling best its own work, and having for this share the greatest proportion of the whole task." The great use of tracing the history of the development of machines is, that the more clear the path along which real advance has come to pass can be laid down, the more clearly we are enabled to see the direction that must be taken by succeeding advances. Probably the earliest machine known is the fire-drill, used in very early days of the development of the human race for producing fire by its rapid rotation between the hands, being at the same time held in firm contact with another flat piece of wood. The improvements on this appear to have been pointing the fire-drill at the other end, enabling the vertical pressure to be supplied by an assistant by means of a flat piece pressed on the top of the drill,

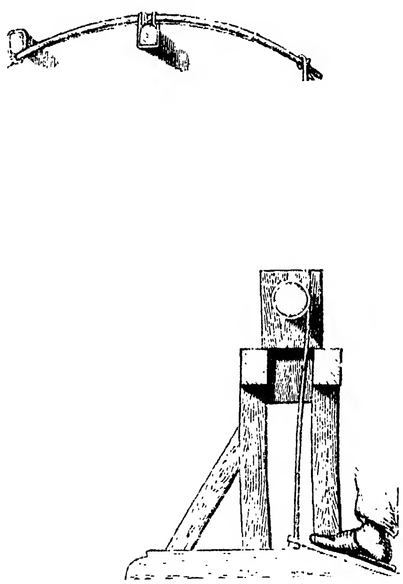

FIG. 5.

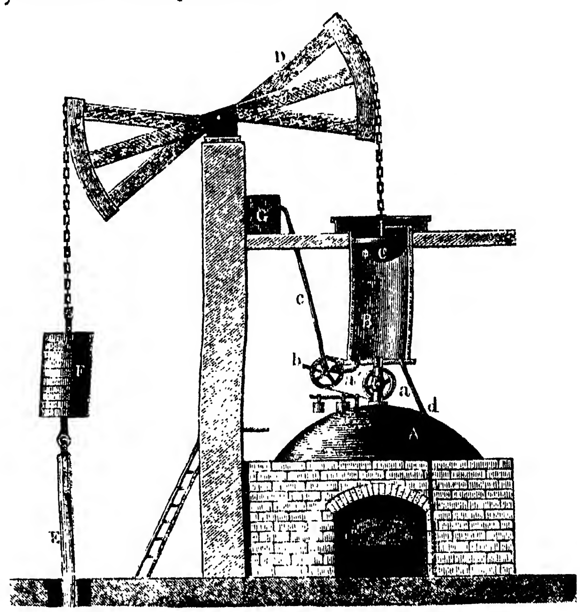

FIG. 6.

and communicating the rotation to the drill by means of a cord wrapped once or twice round it. The applications of this tool seem to have been numerous, as with it hard woods, bone, horn, and even hard stones, appear to have been drilled, no doubt with the assistance of a supply of sand and water. From the fire-drill, probably after a very long interval, sprang the potter's wheel, and the earliest forms of turning-lathe turned in a similar manner; the principle is preserved to the present day in the bow-drill used for light metal-work. The origin of the screw and nut is lost in obscurity, but this pair of elements was certainly known to the Greeks and Romans; Prof. Reuleaux's suggestion of its origin, tracing it to the fire-drill, is very ingenious, even if it is not the right one; that with long-continued use of the drill, the cord may have worn spiral groves on the spindle, forming a screw-thread while the cord itself formed the nut. "The forms of the word screw in the Germanic languages greatly strengthen my suggestion. We cannot take into account the fact that in English and the Romance languages the characteristic portion of the screw is called 'thread' (*filo, filet*),

[1] "The Kinematics of Machinery: Outlines of a Theory of Machines." By F. Reuleaux, Director of and Professor in the Königlichen Gewerbe-Akademie in Berlin, Member of the Königl. technischen Deputation für Gewerbe. Translated and edited by Alex. B. W. Kennedy, C.E., Professor of Civil and Mechanical Engineering in University College, London. (London: Macmillan and Co., 1876.) Continued from p. 214.

for this name may have been subsequently given to it." Again, "The bow of the archer is a machinal organ in which energy is stored; the sensible force of the muscles is made latent in it, and it is this latent energy stored in the elastic bow which actually propels the arrow. In the ballista and catapult this principle receives still more extended application, for in them kinematic means are employed to store the energy of many men, so as to employ it concentrated with correspondingly increased effect. Later on the same principle extends itself to primary forces, and it is to-day more used than ever, from the tiny watch-work or the spring of a gun-lock, through innumerable mechanisms, up to the Armstrong accumulator or the air-vessels of the Mont Cénis borers." But it is from the kinematic point of view that the progress of the development of the machine is most accurately measured. What is the fundamental characteristic of the improvement that has been effected in the various stages of advance in the development of a machine? Prof. Reuleaux answers: "The line of progress is indicated in the manner of using force-closure or more particularly in the substitution of pair closure and the closure of the kinematic chains obtained by it for force-closure." In the fire-drill, which is an early form of turning-pair, we have not only force-closure by the action of the hands in the longitudinal direction, previous to the introduction of the bearing-piece on the top, but also force-closure in the transverse direction by the hands. The invention of the string for turning the drill, itself a great advance, introduces another kinetic pair of elements, but still the string is constrained to keep in contact with the stick by the force-closure of the tension produced by the hands. In the earliest form of lathe with double head-stocks, the force-closure of the double element is changed to pair-closure, marking a great advance in the development of the machine, and the string is worked in a more definite manner by one end being fastened to a bow or spring-beam, whilst the other is worked by the foot (Fig. 5).

"Thus simplicity or fewness of parts does not itself constitute excellence as a machine, but increased exactness in the motions obtained, with diminished demands on the intelligence of any source of energy."

In more recent machinery, such as Newcomen's engine (Fig. 6), we see the connection of the beam D and the pump-rod E, affected by the force-closure of the weight F acting on the chain, the connection of the piston C, and the beam D, affected by force-closure also, by the same weight, whilst the valve-gear was worked by hand.

By the invention of his nearly perfect parallel motion, Watt introduced kinematic pair and chain-closure into the steam-engine, as well as by the introduction of automatic valve-gear. Space will not permit us to give an account of the systems of kinematic notation proposed by Prof. Reuleaux, but it certainly is one of the most important chapters in the book, and will well repay a careful study, although some little time and trouble is evidently required to get the meaning of the various symbols impressed on the memory. When this has been done we have no doubt that it will amply compensate the learner for his pains, by the much more ready comprehension he will obtain of complex mechanisms. We can only say, in the words of our author, "The reader need not fear that any continual alteration of his accustomed ideas will be demanded from him in making himself familiar with the system of contractions. For a scientific symbolic notation is in essence nothing else than a systematised method of contraction—it is not a hieroglyphic system mysterious to the uninitiated." Under the head of analysis of chamber-crank chains, the various disc-engines, rotatory engines and blowers, of which such a large and varied assortment has been from time to time invented, are described and figured, and our author states at the end of the long list so formed that the whole of the forms that have appeared are probably not exhausted, and that "a comparison of the machines described shows, indeed, that there are many easily constructed inversions of existing mechanisms which have not yet been proposed, and many analogies to existing forms which have not been tried; so we may look forward still to the production of whole series of chamber-crank trains by the never resting empirics. In Chapter xi. we come to the machine considered as a combination of constructive elements and the complete enumeration of them, and their systematic classification deserves particular attention. As an example of this classification we may give the double-acting ratchet train (Fig. 7) and the double-

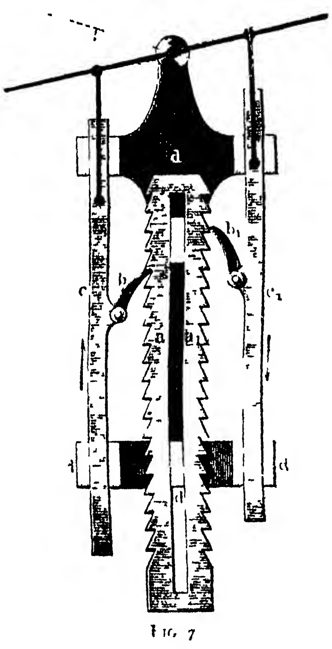

FIG. 7

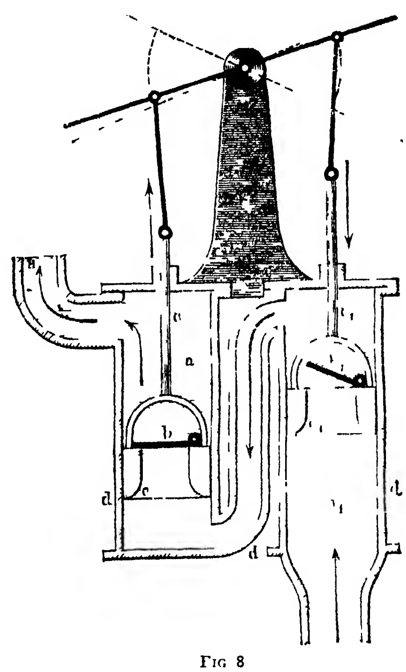

FIG. 8

acting pump (Fig. 8); these are classed together, and a closer examination of the function and elements of each will immediately show the correctness of so doing. The two bars *c* and *c* in the ratchet train correspond with the two pump rods and buckets. The pump barrels *d d* correspond with the guide frames *d d* of the ratchet train, the valves *b* and *b* correspond with the pawls *b* and *b*, while the water in the two barrels is the exact equivalent of the ratchet *a a*. As the bar *c* descends the pawl *b* would pass over a certain number of teeth of the ratchet equal to the number in the length of stroke of *c*, if the bar *c* was disconnected with the lever but as it is, during the descent of *c*, through a certain distance the ratchet is lifted an equal distance by the other pawl *b*; thus we see that each pawl passes over twice as many teeth of the ratchet as correspond to the length of its stroke. This has an exact parallel in the double-acting pump, for there also each bucket in its down stroke moves through a length of water equal to double the length of its stroke. The following is the outline of Prof. Reuleaux' Classification of Constructive Elements :—

Rigid Elements—
- Joints (for forming links) such as rivets, keys, keyed joints.
- Elements in pairs or in links, such as shafts and axles, levers, cranks, &c.

Flectional Elements—
- Tension organs by themselves and used with chain-closure, such as belts, cords.
- Partners of pressure organs such as pistons and plungers, steam cylinders and pump barrels.
- Springs.

Trains—
- Click-gear.
- Brakes.
- Movable couplings and clutches

In conclusion we must say that the cuts illustrating the book, are much superior to those generally to be found in theoretical books on machinery, but they do not, of course, equal the elaborate working drawings to be found in certain books on machine design. In Fig. 169, p. 218, the rope appears to have somewhat lost its way. The translator has done his work most admirably, and great must have been the ingenuity required to manufacture some of the names here presented for the first time to the English reader. In fact we could hardly imagine a book more difficult to translate, on account of the great number of specially-constructed words in it, nor do we remember having read one in which the duties of the translator have been more successfully carried out. The book appears at a particularly suitable time, now that the beautiful and extensive collection of kinematic models by Prof. Reuleaux, designed by him and constructed especially to illustrate his treatment of the theory of mechanism, is to be seen at the Loan Collection of Scientific Instruments at South Kensington.

PERIGENESIS v. PANGENESIS—HAECKEL'S NEW THEORY OF HEREDITY

UNDER the title "Perigenesis der Plastidule oder die Wellenzeugung der Lebenstheilchen," Prof. Haeckel has published quite recently a pamphlet containing an attempt to furnish a mechanical explanation of the elementary phenomena of reproduction which shall be more satisfactory than Mr. Darwin's ingenious and well-known theory of Pangenesis. I shall endeavour to show that Prof. Haeckel's theory is essentially that with which both English and German students of Mr. Herbert Spencer's works have long been familiar; and that it does not furnish a clearer explanation than does Mr. Darwin's Pangenesis, of the special facts of heredity which Mr. Darwin had in view.

Haeckel commences with a very concise statement of what is at present known as to the visible composition of "plastids," those corpuscles of life-stuff called "cells" by Schleiden and Schwann, "elementary organisms" by Brücke, "life-units" by Darwin. Most plastids possess a differentiated central kernel or nucleus, which again possesses one or more nucleoli. The substance of which the body of such a nucleated plastid or *true* cell is mainly composed is generally known by von Mohl's term, "protoplasma." Haeckel proposes to distinguish the substance of the nucleus by the name "coccoplasma." In the simplest form of plastid, the "cytod," which is devoid of nucleus, and is exhibited by those lowly organisms known as Monera, by the young Gregarina (Ed. van Beneden), by the hyphæ of some Fungi, and by the ripe egg of all organisms (if we may judge from the results of the most recent researches), coccoplasm and protoplasm are not differentiated, but exist as one substance, which Haeckel, following Ed. van Beneden, distinguishes as "plasson." Whether these distinctions have a real value or not, is of no moment for the question in hand. It is a widely-accepted doctrine—in fact, the fundamental generalisation on which Biology as a science rests—that the excessively complex chemical compound which forms the substance of plastids or life-units is the ultimate seat of those phenomena or manifestations of energy which distinguish living from lifeless things—to wit, growth by intus-susception, reproduction, adaptation, and continuity or hereditary transmission. Leaving Prof. Haeckel's pamphlet for a time, let us go back thirteen years.

As long ago as July, 1863, Mr. Herbert Spencer, in his "Principles of Biology," pointed out at considerable length (vol. i., p. 181) that the assumption of definite forms, and the power of repair exhibited by organisms, is only to be brought into relation with other facts (that is to say, so far explained) by the assumption that *certain units* composing the living substance or protoplasm of cells possess "polarity" similar to, but not identical with, that of the units which build up crystals. Mr. Spencer is careful to explain that by the term "polarity" we mean simply to avoid a circuitous expression, namely, the still unexplained power which these units have of arranging themselves into a special form. He then points out that the units in question cannot be the molecules of the proximate chemical compounds which we obtain from protoplasm—such as albumen, or fibrin, or gelatin, or even protein. Further he shows that they cannot be the *cells* or morphological units, since such organisms as the Rhizopods are not built up of cells, and since, moreover, "the formation of a cell is to some extent a manifestation of the peculiar power" under consideration. "If then," he continues, "this organic polarity can be possessed neither by the chemical units, nor the morphological units, we must conceive it as possessed by certain intermediate units, which we may term *physiological*. There seems no alternative but to suppose that the chemical units combine into units immensely more complex than themselves, complex as they are; and that in each organism, the physiological units produced by this further compounding of highly compound atoms, have a more or less distinctive character. We must conclude that in each case, some slight difference of composition in these units, leading to some slight difference in their mutual play of forces, produces a difference in the form which the aggregate of them assumes."

Further on Mr. Spencer applies the hypothesis of physiological units to the explanation of the phenomena of heredity, introducing the subject by the following admirable remarks, which appear to me to assign in the most judicious manner, their true value to such hypotheses and to be as strictly applicable to later speculations as to his own. "A positive explanation of heredity is not to be expected in the present state of biology. We

can look for nothing beyond a simplification of the problem, and a reduction of it to the same category with certain other problems which also admit of hypothetical solution only. If an hypothesis which certain other wide-spread phenomena have already thrust upon us, can be shown to render the phenomena of heredity more intelligible than they at present seem, we shall have reason to entertain it. The applicability of any method of interpretation to two different but allied classes of facts is evidence of its truth. The power which organisms display of reproducing lost parts, we saw to be inexplicable except on the assumption that the units of which any organism is built have an innate tendency to arrange themselves into the shape of that organism. We inferred that these units must be the possessors of special polarities, resulting from their special structures; and that by the mutual play of their polarities they are compelled to take the form of the species to which they belong. And the instance of the *Begonia phyllomaniaca* left us no escape from the admission that the ability thus to arrange themselves is latent in the units in every undifferentiated cell. . . . The assumption to which we seem driven by the *ensemble* of the evidence, is that sperm-cells and germ-cells are essentially nothing more than vehicles, in which are contained small groups of the physiological units in a fit state for obeying their proclivity towards the structural arrangement of the species they belong to. . . . If the likeness of offspring to parents is thus determined, it becomes manifest, *a priori*, that besides the transmission of generic and specific peculiarities, there will be a transmission of those individual peculiarities which, arising without assignable causes, are classed as 'spontaneous'. . . .

"That changes of structure caused by changes of action must also be transmitted, however obscurely, from one generation to another, appears to be a deduction from first principles—or if not a specific deduction, still, a general implication. . . . Bringing the question to its ultimate and simplest form, we may say that as on the one hand physiological units will, because of their special polarities, build themselves into an organism of a special structure, so on the other hand, if the structure of this organism is modified by modified function, it will impress some corresponding modification on the structures and polarities of its units. The units and the aggregate must act and re-act on each other. The forces exercised by each unit on the aggregate, and by the aggregate on each unit, must ever tend towards a balance. If nothing prevents, the units will mould the aggregate into a form in equilibrium with their pre-existing polarities. If contrariwise, the aggregate is made by incident actions to take a new form, its forces must tend to re-mould the units into harmony with this new form; and to say that the physiological units are in any degree so re-moulded as to bring their polar forces towards equilibrium with the forces of the modified aggregate, is to say that when separated in the shape of reproductive centres, these units will tend to build themselves up into an aggregate modified in the same direction." (P. 256.)

Thus, then, Mr. Herbert Spencer definitely assumes an order of molecules or units of protoplasm—lower in degree than the visible cell-units or plastids—to the "polar forces" of which and their modification by external agencies and interaction, he ascribes the ultimate responsibility in reproduction, heredity, and adaptation.

I am unable to say whether Mr. Darwin was acquainted with or had considered Mr. Herbert Spencer's hypothesis of physiological units, when in 1868 he published his own provisional hypothesis of Pangenesis. But an examination of the bearings of the two hypotheses shows that the former does not render the latter superfluous, nor is the one inconsistent with the other. Mr. Darwin wished to picture to himself and to enable others to picture to themselves a process which would account for (that is, hold together and explain) not merely the simpler facts of hereditary transmission, but those very curious though abundant cases in which a character is transmitted in a latent form and at last reappears after many generations, such cases being known as "atavism" or "reversion;" and again those cases of latent transmission in which characteristics special to the male are transmitted to the male offspring through the female parent without being manifest in her; and yet again the appearance at a particular period of life of characters inherited and remaining latent in the young organism. According to the hypothesis of pangenesis, "every unit or cell of the body throws off gemmules or undeveloped atoms, which are transmitted to the offspring of both sexes and are multiplied by self-division. They may remain undeveloped during the early years of life or during successive generations; their development into units or cells, like those from which they were derived, depending on their affinity for, and union with, other units or cells previously developed in the due order of growth."

In an essay ("Comparative Longevity," Macmillan, 1870, p. 32) published six years ago, I briefly suggested the possibility of combining Mr. Herbert Spencer's and Mr. Darwin's hypotheses thus: "The persistence of the same material gemmule and the vast increase in the number of gemmules, and consequently of material bulk,[1] make a *material* theory difficult. Modified force-centres, becoming further modified in each generation, such as Mr. Spencer's physiological units, might be made to fit in with Mr. Darwin's hypothesis in other respects." In fact in place of the theory of emission from the constituent cells of an organism of material gemmules which circulate through the system and affect every living cell, and accumulate in sperm-cells and germ-cells, we may substitute the theory of emission of force, the two theories standing to one another in the same relation as the emission and undulatory theories of light.

It may, however, be very fairly questioned whether our conceptions of the vibrations of complex molecules, or in other words their force-affections, are sufficiently advanced to render it desirable to substitute the vaguer though possibly truer undulatory theory of heredity for the more manageable molecular theory (Pangenesis). How are we to conceive of the propagation of such states of force-affection or vibration (as they are vaguely termed) through the organism from unit to unit? In what manner, again, are we to express the dormancy of the pangenetic gemmules in terms of molecular vibration? It is true that molecular physics furnishes us with some analogies in the matter of the propagation of particular states of force-affection from molecule to molecule, as, for example, in the various modes of decomposition exhibited by gun-cotton, in contact actions and the like; but it will require a very extended analysis of both the phenomena of heredity and of molecular phenomena similar to those just cited, to enable us to supersede the admittedly provisional hypothesis of Pangenesis by a hypothesis of vibrations. And it is necessary here to remark that in the fundamental conception of Pangenesis, namely, the detachment from the living cells of the organism of gemmules which then circulate in the organism, there is nothing contrary to analogy, but rather in accordance with it. It is quite certain that in some infective diseases the contagion is spread by specific material particles. This seems to be established, although it is far from settled as to whether these particles are parasitic organisms or portions of the diseased organism itself. Mr. Darwin's pangenetic gemmules may, even if not accumulated and transmitted from generation to generation, be called upon to explain the solidarity of the constituent cells of one organism; they may be assumed as agents of

[1] On this subject see Mr. Sorby's recent Presidential Address to the Royal Microscopical Society, in "Quarterly Journal of Microscopical Science," April, 1876.

a peculiar kind of infection,[1] by means of which the molecular condition or force affection of one cell is communicated to others at a distance in the same organism. It is difficult without some such hypothesis of an active material exchange of living molecules between the various cells of the body, to conceive of the way in which "change is propagated throughout the parental system," or a modified part is to "impress some corresponding modification on the structures and polarities" of distant units, such, for example, as those contained in the mammalian ovum.

In the human ovary no egg-cells are produced after the age of two and a half years. Each of the many hundred eggs there contained reposes quietly in its follicle, whilst the growth and development of other organs is proceeding. Then a renewed period of activity for the ovary commences, but the majority of the originally-formed egg-cells retain their vitality and form-individuality for more than forty years. How, we may ask, during that time are they subjected to the influence of new polar forces acquired by the other units of the body? We know that they are so impressed, or have such influences propagated to them. Is it by "action at a distance," or by the contact action of circulating infective gemmules?

Such being the state of speculation, in England at any rate, with regard to the mechanical explanation of heredity, we return to Prof. Haeckel's recently enunciated theory of the Perigenesis of plastidules.

It is clear, to begin with, that Prof. Haeckel has either never studied or has forgotten Mr. Herbert Spencer's writings. His attempt to substitute something better for Mr. Darwin's provisional hypothesis of Pangenesis, as he tells us, has its origin, to a great extent, in the admirable popular lecture of Prof. Ewald Hering of Prague, "Über das Gedachtniss als eine allgemeine Function der organisirten Materie" [On Memory as a General Function of Organised Matter], published in 1870, and to some extent, including terminology, is based on an essay by Elsberg, of New York, published in the *Proceedings* of the American Association, Hartford, 1874. With the latter of these publications I am only acquainted through Prof. Haeckel's citations, but with the former at first hand. Prof. Hering gives a brief outline in the lecture in question, of the fundamental doctrine of physiological psychology, which had been previously worked out to its consequences on an extensive scale, by Mr. Herbert Spencer. Prof. Hering has the merit of introducing some striking phraseology into his treatment of the subject, which serves to emphasise the leading idea. He points out that since all transmission of "qualities" from cell to cell in the growth and repair of one and the same organ, or from parent to offspring, is a transmission of vibrations or affections of material particles, whether these qualities manifest themselves as form, or as a facility for entering upon a given series of vibrations, we may speak of all such phenomena as "memory," whether it be the conscious memory exhibited by the nerve-cells of the brain or the unconscious memory we call habit, or the inherited memory we call instinct; or whether again it be the reproduction of parental form and minute structure. All equally may be called "the memory of living matter." From the earliest existence of protoplasm to the present day, the memory of living matter is continuous. Though individuals die, the universal memory of living matter is still carried on.

Prof. Hering, in short, helps us to a comprehensive conception of the nature of heredity and adaptation by giving us the term "memory," conscious or unconscious, or the continuity of Mr. Herbert Spencer's polar forces or polarities of physiological units.

[1] It is a striking exemplification of the unity of biological science that we should have to look to the pathologist for the next step in this region of speculation, and that fermentations, phosphorescence, fevers, and heredity, should be simultaneously studied from a common point of view with psychology.

Elsberg appears (though this is only an inference on my part) to be acquainted with Mr. Herbert Spencer's hypothesis of physiological units. Adopting Haeckel's useful term "plastid" for a corpuscle of protoplasm (cell or cytod), he designates the physiological units "plastidules," a name which Haeckel has accepted, and which may very possibly be found permanently useful. But Elsberg does not appear to have helped on the discussion of the subject to a great extent, since he proceeds no further than is implied in adopting Mr. Darwin's theory of Pangenesis, whilst substituting the "plastidules" for Mr. Darwin's "gemmules." It appears to me that Elsberg, in his combination of the Spencerian and Darwinian hypotheses, has omitted the sound element in the latter, and retained the more questionable. He should have conjoined Mr. Herbert Spencer's conception of "plastidules" possessing special polarities or force affections which they are capable of propagating as *changes* of state (*i.e.*, force-waves) to associated plastidules, and so to offspring with Mr. Darwin's conception of a universal and continuous emission of such changes from all the cells of an organism, and the frequent occurrence of a persistently latent condition of those changes—a condition which Hering's happy use of the term "memory" enables us to illustrate by the analogous (or we should rather say identical) "latent" or "dormant condition" of mental impressions.

This is, in fact, the position which Prof. Haeckel takes up—though independently of what Mr. Spencer has written on the subject, excepting so far as the influence of the latter is to be traced in Elsberg's essay. For Haeckel, living matter, protoplasm, or plasson consists of definite molecules—the plastidules which cannot be divided into smaller plastidules, but can only be split into lower chemical compounds. What Mr. Spencer calls polarities or polar forces Haeckel speaks of as "undulatory movements"—a symbol which has the advantages and disadvantages of analogy, but which, like "polarity," is *only* a symbol, and covers our incapability of conceiving more definitely the character of the phenomenon it designates. The undulatory movement of the plastidules is the key to the mechanical explanation of all the essential phenomena of life. The plastidules are liable to have their undulations affected by every external force, and once modified the movement does not return to its pristine condition. By assimilation they continually increase to a certain point in size, and then divide, and thus perpetuate in the undulatory movement of successive generations the impressions or resultants due to the action of external agencies on individual plastidules. This is Memory. All plastidules possess memory—and Memory, which we see in its ultimate analysis is identical with reproduction, is the distinguishing feature of the plastidule; is that which it alone of all molecules possesses in addition to the ordinary properties of the physicist's molecule; is in fact that which distinguishes it as vital. To the sensitiveness of the movement of plastidules is due Variability—to their unconscious Memory the power of Hereditary Transmission. As we know them today, they may "have learnt little and forgotten nothing" in one organism, "have learnt much and forgotten much" in another, but in all, their Memory, if sometimes fragmentary, yet reaches back to the dawn of life on the earth.

E. Ray Lankester

Addendum.—It will interest many readers to know that Prof. Haeckel takes an opportunity in this pamphlet of referring to Bathybius. He does not allude to the report from the *Challenger*, to the effect that Bathybius is a gelatinous precipitate of sulphate of lime, but speaks of it as of old. He draws attention to the recent observations of an excellent naturalist, Dr. Bessels, who, I find, in the *Jenaische Zeitschrift*, 1875, vol. ix. p. 277, writes as follows:—"During the last American expedition to the North Pole, I found, at a depth of ninety-two fathoms in

Smith's Sound, large masses of free, undifferentiated, homogeneous protoplasm which contained no trace of the well-known coccoliths. On account of its truly Spartan simplicity, I called this organism, *which I was able to observe in the living state*, 'Protobathybius.' It will be figured and described in the Report of the expedition. I will merely state here that these masses consisted of pure protoplasm, with only accidental admixture of calcareous particles, such as formed the sea-bottom. They formed exceedingly viscid, net-like structures, which exhibited beautiful amœboid movements, took in carmine-particles as well as other foreign bodies, and showed active granule-streaming."

This is certainly a very deliberate and definite statement on the part of Dr. Bessels, who is a well-known and accomplished observer. It will be interesting to see how these observations can be reconciled with the view taken by Sir C. Wyville Thomson and Mr. Murray.

DINNER TO THE "CHALLENGER" STAFF

ON Friday last, Sir C. Wyville Thomson and other members of the *Challenger* staff were entertained at dinner in the Douglas Hotel, Edinburgh, by a large and distinguished company. Besides the civilian chief himself, the other members of the staff present were Mr. J. Y. Buchanan, Mr. J. Murray, Lieut. Balfour, Dr. Crosbie, and Paymaster Richards. The Lord Provost occupied the chair, the croupiers, as the vice chairmen are called in Scotland, being Professors Huxley and Turner. The speeches were unusually happy and spirited, but we have space to give only a few quotations from that of Prof. Huxley in proposing the health of the scientific staff of the *Challenger*, and their director, Sir C. W. Thomson. After referring to previous Government expeditions for ocean exploration, Prof. Huxley pointed out that the peculiarity of the *Challenger* Expedition was that in her case the cruise became secondary and the scientific object primary; that she was, in fact, fitted up and instructed with the view of obtaining certain scientific data which were requisite for the further progress of natural knowledge. In her case the duty of geographical exploration was reduced to *nil*, and the duty of scientific investigation had become paramount.

After showing the great importance of a knowledge of the nature of the sea-bottom, Prof. Huxley went on—

"Thirty years ago it would have been absolute madness for anyone—I was going to say—to have hoped to obtain any knowledge of the nature of the sea-bottom or of the things which lived there at depths of 5,000, 6,000, 15,000, or 20,000 feet. But then here comes one of those admirable examples of the way in which the theoretical life of this world and the practical life interlock with one another, and interact with one another. Theoretical science, abstract investigation, carried on without reference to any practical aim whatever, that sort of abstract investigation which recent Acts of Parliament have endeavoured to throw a slur upon in this country, though I am happy to say that that has been removed in the House in which it originated—that kind of abstract investigation without immediate practical result, gave us the electric telegraph. When the electric telegraph was got, practical men desired to use it as a means of connecting remotely removed countries. For that purpose it was necessary to lay submarine telegraphs. For that purpose it was necessary to improve our means of sounding; and so out of the electric telegraph came those means of sounding at great depths of the sea, which have enabled us, for the first time, to bring up from the bottom, from a depth of two or three, or it may be four miles of sea-water, the actual things which are to be found at that enormous depth. That took place twenty years ago. In 1858, my friend Commander Dayman was engaged in the survey of the Atlantic for the purposes of the cable; and the Americans, who joined in the like service, had invented means by which specimens could be brought up from that depth. So that, if I may so say, ten years ago it was in the air to apply those new methods supplied by practical life to scientific purposes, to apply the methods of sounding, the methods of dredging, and the methods of ascertaining temperature which had been devised for the purposes of the telegraph engineer, to further investigation of the contents and nature of the sea. But it is all very well for ideas to be in the air. It needs clear brains to get them out of the air, and in this case there were two very clear brains at work on the subject—one of them the brain of our distinguished guest of to-night, Sir C. Wyville Thomson—and the other the brain of my friend Dr. Carpenter, who is well known to the scientific world."

Prof. Huxley then referred briefly to the history of recent deep-sea exploration and to the influences brought to bear on the Admiralty to send out the *Challenger*. He spoke of the object of the expedition and of the important results which have been achieved. "It was a very considerable task," he said, "it was a task which would have been absolutely chimerical thirty years ago, but it was a task which had been rendered possible, and which has been actually performed in the most satisfactory manner. The *Challenger* has brought home, I am informed, the records of such operations performed at between 300 and 400 stations—that is to say, at 300 or 400 points along that 70,000 miles, we know exactly the depth of the sea, the gradations of temperature, the distribution of superficial life, and the nature of what constitutes the sea-bottom; and such a foundation as that for all future thought upon the physical geography of the sea up to this moment not only had not existed, but had not even been dreamed of. I won't detain you by speaking of the great results of the expedition, for one very good reason, that I don't know them. They are in the breast of my friend at the opposite end of the table. But he has been good enough to favour us at the Royal Society from time to time with reports of what he has been about, and some of the discoveries which have been made by the *Challenger* are undoubtedly such as to make us all form new ideas of the operation of natural causes in the sea. Take, for example, the very remarkable fact that at great depths the temperature of the sea always sinks down pretty much to that of freezing fresh water. That is a very strange fact in itself, a fact which certainly could not have been anticipated *à priori*. Take, again, the marvellous discovery that over large areas of the sea the bottom is covered with a kind of chalk, a substance made up entirely of the shells of minute creatures—a sort of geological shoddy made of the cast-off clothes of those animals. The fact had been known for a long time, and we were greatly puzzled to know how those things got to be there. But the researches of the *Challenger* have proved beyond question, as far as I can see, that the remains in question are the shells of organisms which live at the surface and not at the bottom, and that this deposit, which is of the same nature as the ancient chalk, differing in some minor respects but essentially the same, is absolutely formed by a rain of skeletons. These creatures all live within 100 fathoms of the surface, and being subject to the fate of all living things, they sooner or later die, and when they die their skeletons are rained down in one continual shower, falling through a mile, or couple of miles of sea-water. How long they take about it imagination fails one in supposing, but at last they get to the bottom, and there, piled up, they form a great stratum of a substance which, if upheaved, would be exactly like chalk. Here we have a possible mode of construction of the rocks which compose the earth of which we had previously no conception. But this is by no means the most wonderful thing. When they got to depths of 3,000 and 4,000 fathoms, and to 4,400 fathoms, or about five miles, which was the greatest depth at which the *Challenger* fished anything from the

bottom—and I think a very creditable depth too—they found that, while the surface of the water might be full of these calcareous organisms, the bottom was not. There they found that red clay so pathetically alluded to by my friend on the right [Commander Stewart, who replied for the Navy] as the material to which when glory called him he might be reduced. This red clay is a great puzzle—a great mystery—how it comes there, what it arises from, whether it is, as the director has suggested, the ash of foraminiferæ; whether it is decomposed pumice-stone vomited out by volcanoes, and scattered over the surface, or whether, lastly, it has something to do with that meteoric dust which is being continually rained upon us from the spaces of the universe—which of these causes may be at the bottom of the phenomenon it is very hard to say; it is one of those points on which we shall have information by-and-by. I will not detain you further with speaking of the matters of interest which have come out of this cruise of the *Challenger*; I will only in conclusion remind you that work of this kind could by no possibility be done without the zealous aid of an intelligent executive. That is the first condition, but our thanks have already been rendered to the executive officers of the *Challenger*. In the second place, it could only have been done by the aid of such a scientific staff, composed of picked men as was sent out in the *Challenger*, such men as Buchanan, Murray, and Moseley, and Wild, and Suhm; and I can hardly mention the name of the last gentleman without, in passing, lamenting that he alone of all the staff who left our shores,—he who certainly was the last person we should have imagined we should not see again—that a man of his accomplishments and promise and geniality and lovability should be the only one not to be welcomed back by the friends who loved him, and by the country which would have been glad to adopt him. But, again, a work such as has been done by the *Challenger* could only have been effectively carried out under the direction, not only of a man who intellectually knew what he was about, but whose moral qualities were such as to get the people with whom he was associated to work with him."

Prof. Huxley concluded by referring to the harmony which throughout prevailed among the staff of the *Challenger*.

"When men are shut up together in a limited society, whether it be a cathedral town or a ship, they begin to hate one another unless the bishop is a very wise person. In this case I do not doubt that the bishop was a very wise person, and I do not believe that the whole course of the *Challenger* afforded occasion for any such triangular duels as one hears of in the novels of Captain Marryat."

Sir C. Wyville Thomson made a suitable reply to the toast, giving a brief account of the various operations of the *Challenger*, and referring to the great amount of work yet to be done ere all the results could be given to the world.

PHOTOGRAPHIC PROCESSES[1]

IT is not my intention to enter into the history of any of the processes to which I propose to call your attention to-night, as I somewhat dread to enter upon such controversial ground. Probably the demonstration of the production of photographic prints by various methods will be of greater interest than any history.

Astronomy was the religion of the world's infancy, and it can hardly be a matter of surprise that untutored yet inquiring minds, unaided by any distinct revelation, should have attributed to the glorious orb, the centre of our solar system, the possession of divine attributes, and as they gazed upon the wondrous effects of his magical painting, that they should have offered to him their adoration and worship, and carefully noted any phenomena due to him. Thus probably the first photographic action noticed would be at a very early period of human existence, when the exposure of the epidermis to his rays caused what is known to us as tan, whilst the parts of the body covered would remain of their pristine whiteness. A photographic action which would be remarked at a later date would be the fading of colours in the sunlight. Ribbons, silks, curtains, and similar fabrics of a coloured nature undergo a change in tint when exposed to it.

I have here a specimen of a pink trimming used by the fair sex, and the lady who presented me with it informed me that it was "a most abominable take in," as the colour "goes" after two days' wear. Her ideas on the subject and my own somewhat differed, for to me it presented a capital opportunity of using the material as a means for obtaining a photographic print in a moderate time. I have here two results of the exposure of this stuff to the sunlight. One was exposed beneath a negative of an anatomical subject, and we have the image represented as white upon a pink ground. The other subject is a map. An ordinary map was superposed over a square piece of the stuff, and placed in sunlight whilst in contact. We have in this case the lines of the map represented as pink on a white ground, from which the colour had faded.

The general opinion is, I believe, that the colour is given off somewhat similarly to the scent from a rose. Were this entirely the case, the light would not act as it does, but beneath the negative or map, the colour would bleach uniformly. The bleaching seems to be a really chemical change in the dye due to the impact of light. There are many other bodies besides dyes which change in light, and some of them are of the most unlikely nature. I had intended to show you to-night the change that takes place in glass by exposure to light for long periods. My friend, Mr. Dallmeyer, has in his possession specimens of brown and flint glass, which have markedly changed colour in those halves of the prisms purposely exposed to solar influences. In some cases there is a "yellowing" of the body, and in others a decided "purpling."

It is, however, only those bodies which change rapidly in the light that are utilised in photography. The most common amongst these are various compounds of silver, for they are peculiarly sensitive to the action of light. Nearly every silver compound is more or less changed by it, and when I say changed I mean altered in chemical composition. When we reflect what light is we can better understand its action. Light, as experiment, confirmed by mathematical investigation, tells us, is caused by a series of waves issuing from the luminous source, not, indeed, trembling in our tangible atmosphere, but in a subtler and infinitely less dense medium, which pervades all space, and which exists even in the interior of the densest solids and liquids. These waves of ether, as this medium is called, batter against and try to insinuate themselves amongst the molecules of any body exposed to their action, a good many millions of millions of them impinging every second against it. Surely it is not surprising to think, small though the lengths of these waves be, that this persistent battering should in some instances be able to drive away from each of the molecules some one of the atoms of which they are composed.

Take as a type that salt of silver which was, perhaps, the first known to change in the presence of light-silver chloride. For our purpose we may represent each of its molecules as made up of two atoms of silver locked up with two atoms of chlorine. Let us consider the action of the light on only one molecule. The waves strike against it energetically and persistently; the swing that the molecule can take up is not in accord with the swing of the ether. It is shaken and battered till it finally gives up one atom of chlorine; the vibration of the remaining two atoms of silver and one of chlorine are of a different period, and are not sufficiently in discord to cause a further elimination of an atom. The molecule which contains the two atoms of silver and one of chlorine is called a sub-chloride of silver or argentous chloride, and is of a grey violet colour. If, then, I place silver chloride (held in position by a piece of paper) beneath a body, part of which is opaque and part transparent, and expose it to sunlight, I shall find that where the opaque parts cover it, there the white chloride will remain unchanged, whilst on the portions beneath the transparent parts, the dark silver sub-chloride will have been formed. Of course were the paper, after removal of the body, to be further exposed to light, the image obtained would disappear, as a blackening over the whole surface would ensue. In this state, then, the print is not permanent. Fortunately for photography, a ready solvent of silver chloride was

[1] Lecture by Capt. Abney, R.E., F.R.S., at the Loan Collection, South Kensington.

found by Sir John Herschel in sodium-hyposulphite. On applying this salt to the image, it was removed, and also one atom of silver and one of chlorine from the sub-chloride molecule, leaving the atom of metallic silver behind. The chemical change that takes place on the silver chloride can be very distinctly shown by exposing it perfectly pure beneath water. The presence of the sub-chloride is shown by the colour, and that of the chlorine can be exhibited by the usual chemical tests.

In making an ordinary silver print on paper, we have, however, something more present than silver chloride; we have an organic salt known as the albuminate of silver, that is, a combination between albumen and silver. I have in this test-tube a little dilute albumen—the solid constituent of the white of an egg. Into it I drop a little silver nitrate: a flocculent precipitate is at once apparent. The silver from the nitrate has combined with the albumen, and on burning a piece of magnesium wire before it the outer surface shows a darkening; evidently, then, the albuminate of silver is decomposed by light. For silver printing purposes, paper is coated on one surface with a solution of albumen and sodium chloride, and the production of the silver chloride and albuminate is effected by floating that surface on a solution of silver nitrate. When dry, the paper which is now sensitive to light is ready for exposure beneath a negative. Here we have two prints produced on paper so prepared. If now I take one of them and dissolve away the insoluble salts in sodium hyposulphite, you see that the colour is of a disagreeable foxy-red tint. To show you how this want of a pleasing tone may be overcome, the other print is immersed in a weak solution of gold, and by a well-known chemical action the metallic gold is deposited on the darkened portions of the picture. Now when gold is precipitated, it has not the well-known yellow colour, but is of a bluish purple; thus the deposited gold mixes its peculiar tint with that of the silver, and after immersion in the hyposulphite we obtain a print whose beauty cannot be surpassed.

I daresay that many of you may have been charmed with the production of magic photographs, as they were called. Some few years ago the sale of such was enormous, but now the curiosity of the public seems to be satiated. The magic, as you may be aware, consisted in being able to produce on a white piece of paper a photograph of some unknown object. These mysterious pieces of paper were generally supplied in packets, containing with them a piece of blotting-paper. The directions stated that the blotting-paper was to be damped, and whilst moist, to be applied to the surface of one of the accompanying pieces of blank paper, and then a photograph would shoot out. I will endeavour to show you one method of their production. Here I have an ordinary photographic print which has not been treated with gold, but merely immersed in sodium hyposulphite and then washed. I immerse it in a solution of mercurous chloride which I have in this dish, and immediately a bleaching action is set up. The action continues, and the paper is apparently blank. What has happened? Simply a white compound of silver and mercury has been formed, which is indistinguishable from the paper. If I wash the paper and dry it, it is in the state of the paper supplied in the packets. I have one here washed and dried, and I immerse it in the sodium hyposulphite. The image immediately reappears, a combination has taken place between the constituents of the hyposulphide, the mercury, and the silver.

Need I say that the blotting-paper supplied is impregnated with the same sodium salt? In damping it the molecules of the latter are so separated and mobile, that they are free to combine with the white image. By similar treatment the picture may be made to again disappear and once more reappear.

Besides silver there are various other metals which will give a photographic image. This paper, which has a slightly yellow tint, has been brushed over with ferric chloride, more commonly known as perchloride of iron, in which we have the maximum number of colours of chlorine combined with metallic iron. Allowing ordinary white light to act upon it, the waves cause a disturbance between the iron and the chlorine atoms, and one of the latter is shaken off, leaving ordinary ferrous chloride, or muriate of iron behind. A piece of paper, similarly prepared, has been exposed beneath a negative, and the reduction of the ferric chloride to the ferrous state can be demonstrated by floating it on a solution of potassium ferricyanide. The combination between the lowest type of the iron salt and this salt results in the formation of a deep blue precipitate known as Turnbull's blue. You see, after applying it, we have the lines of this map, of which this is the negative, of an intense blue. Instead of demonstrating the change of the iron salt by this means, I may float it on a weak solution of silver nitrate. The ferrous salt of iron will reduce the silver, whilst the ferric salts are wholly inoperative to produce the same effect. Here we have such a print.

The principal investigator of the action of light on iron compounds was Sir John Herschel, and he employed a variety of different combinations. Perhaps one of the most interesting exhibits in the Photographic Section is that old list of Fellows of the Royal Society on which were pasted, by the hand of that distinguished philosopher, the actual solar spectrum prints made during his researches on these and other metallic salts.

Uranium salts are also capable of being reduced to less complex forms by the action of light. I will not enter into a detailed description of the decomposition, but will simply exhibit the method of producing a print with the salt. The paper has been coated with uranic nitrate and exposed to light, beneath the same negative before shown to you. The image is made visible by a solution of potassium ferricyanide, as in the case of the iron salt.

In the cases of photographs are shown some interesting specimens of iron and uranium prints, made by Nièpce de St. Victor. I believe they were presented to Sir Charles Wheatstone by that ardent experimentalist. The subdued brown tones of the latter were probably obtained by the admixture of a little iron with the uranium.

Within the last couple of years the salts of iron have been put to practical photographic printing purposes by Mr. W. Willis, jun., of Birmingham, and a valuable process has resulted from his labours. The sensitive salt employed is an organic salt of iron known as ferric oxalate, and Mr. Willis made the discovery that amongst other metals platinum could be reduced to the metallic state from a double chloride of potassium and platinum, by ferrous oxalate in the presence of a potassic oxalate. A piece of paper is floated on a weak solution of silver nitrate and dried; and over the surface is brushed a mixture of the platinum salt and the ferric oxalate. After exposure to light (which produces the ferrous salts) beneath a negative, the paper is floated on a solution of neutral potassium oxalate, when the image at once appears formed of platinum black, a substance at once durable and incapable of being acted upon by atmospheric influence. Such an exposed paper I have here, and floating it on oxalate solution, you see the image is immediately developed. The unreduced iron salt can be eliminated by soaking the print in the oxalate solution, and a rinse and hyposulphite removes all traces of silver nitrate. After a few changes of water, the print may be dried, and is permanent. I should explain that the paper is first coated with silver nitrate in order to cause the platinum to adhere firmly to the surface of the paper. When omitted, the fine black powder formed is apt to precipitate in the bath.

Before dwelling upon that metallic compound which in photography is next in importance to silver, I must call your attention to the first vanadium print ever produced. Prof. Roscoe, who has already delighted an audience in this room with an admirable lecture on Dalton's apparatus and what he did with it, has made a classical investigation of the compounds of this metal, and amongst other interesting facts, has noticed that the vanadium salts are reduced by light in a somewhat similar manner to the uranium salts.

We now have to consider the printing processes which are due to the action of light on the dichromates of the alkalis in the presence of organic matter. For our purpose to-night we may take as a type potassium dichromate, a salt which readily parts with its oxygen to those compounds that have an avidity for it, more especially to certain carbon compounds under the influence of the ether waves.

To show that this salt is thus easily reducible by light in the presence of organic matter, I have here a piece of paper which has been brushed over with it, and exposed beneath a print. For a moment I float it on a weak solution of silver nitrate. The brilliant crimson colour of the part not exposed to light tells us that silver dichromate has been formed, but where the solar rays have acted, the colour remains unchanged. A slight modification of this process now exhibited to you is known as the chromatype, the offspring of Mr. Robert Hunt, so well known in the scientific world for his researches on light. Whilst experimenting with the chromatype process, Mr. W. Willis, the father of the gentleman I have already mentioned, discovered what is known as the aniline process. It is based on the fact that an acid in the presence of potassium

dichromate strikes a blackish green or red colour when brought in contact with aniline. You will see the *modus operandi* when I say that paper is floated with potassium dichromate and a trace of phosphoric acid. Aniline is dissolved in spirits of wine, and the mixed vapours allowed to come in contact with the sensitive paper that has been exposed beneath a positive print, such as a map or plan. The impact of the light has so changed the potassium salt, that the aniline vapour causes but little coloration, whilst where the paper has been protected from it, the dark colour indicates that the dichromate is unchanged. The formation of this black colour is familiar to the manufacturers of aniline colours, being, I believe, similar in composition to the residue left after the formation of aniline purple by Mr. Perkins's method.

It should be noted that for copying engineers' tracings and drawings this process is extremely valuable, as there is no occasion to take a negative on glass before obtaining a print. All that is requisite is that the original should be fairly penetrable by light. A piece of paper prepared as indicated, a sheet of glass to place over the plan, and a box in which to place the exposed print to the aniline vapour are the only necessary plant for the reproduction of a design.

(*To be continued.*)

NOTES

THE following are the officers of the forty-sixth annual meeting of the British Association which will commence at Glasgow on Wednesday, September 6, 1876:—President-designate—Prof. Thomas Andrews, M.D., LL.D., F.R.S., Hon. F.R.S.E., in the place of Sir Robert Christison, Bart., M.D., D.C.L., F.R.S.E., who has resigned the Presidency in consequence of ill health. Vice-Presidents elect—His Grace the Duke of Argyll, K.T., F.R.S., &c., the Lord Provost of Glasgow, Sir William Stirling Maxwell, Bart., M.A., M.P., Prof. Sir William Thomson, D.C.L., F.R.S., &c., Prof. Allen Thomson, M.D., LL.D., F.R.S., &c., Prof. A. C. Ramsay, LL.D., F.R.S., &c. General Secretaries—Capt. Douglas Galton, C.B., D.C.L., F.R.S., &c., Dr. Michael Foster, F.R.S. Assistant General Secretary—George Griffith, M.A., F.C.S. General Treasurer—Prof. A. W. Williamson, Ph.D., F.R.S. Local Secretaries—Dr. W. G. Blackie, F.R.G.S., James Grahame, J. D. Marwick. Local Treasurers—Dr. Fergus, A. S. M'Clelland. The Sections are the following:—Section A: Mathematical and Physical Science. President—Prof. Sir W. Thomson, D.C.L., F.R.S. Section B: Chemical Science. President—W. H. Perkin, F.R.S. Section C: Geology. President—Prof. J. Young, M.D. Section D: Biology. President—A. Russell Wallace, F.L.S. Department of Anthropology, A. Russell Wallace, F.L.S. (President), will preside. Department of Zoology and Botany, Prof. A. Newton, F.R.S. (Vice-President), will preside. Department of Anatomy and Physiology, Dr. J. G. M'Kendrick (Vide-President), will preside. Section E: Geography. President—Capt. Evans, C.B., F.R.S., Hydrographer to the Admiralty. Section F: Economic Science and Statistics. President—Sir George Campbell, K.C.S.I., M.P., D.C.L. Section G: Mechanical Science. President—C. W. Merrifield, F.R.S. The First General Meeting will be held on Wednesday, Sept. 6, at 8 p.m. precisely, when Sir John Hawkshaw, C.E., F.R.S., will resign the chair, and Prof. Andrews, F.R.S., President Designate, will assume the Presidency, and deliver an Address. On Thursday evening, Sept. 7, at 8 p.m., there will be a *soirée*; on Friday evening, Sept. 8, at 8.30 p.m., a Discourse; on Monday evening, Sept. 11, at 8.30 p.m., a Discourse by Prof. Sir C. Wyville Thomson, F.R.S.; on Tuesday evening, Sept. 12, at 8 p.m., a *soirée*; on Wednesday, Sept. 13, the Concluding General Meeting will be held at 2.30 p.m. The Local Committee, as our readers will have seen from a previous report, have made unusual exertions to render the Glasgow meeting a success. A variety of interesting collections will be exhibited, and the excursions which have been already arranged for will doubtless form one of the most attractive, and not the least instructive, feature of the meeting.

IT is with sincere regret that we notice the announcement in *L'Explorateur* of the death of the eminent and well-known geographer, Dr. August Heinrich Petermann, at the early age of fifty-four years. He was born April 18, 1822, at Bleicherode, in Prussian Saxony. In 1839 he became a pupil of the special Academy founded at Potsdam by the geographer Berghaus, whose secretary and librarian he was for six years, as well as *collaborateur*, for he took an active part in the preparation of the great Physical Atlas of his master; the English edition, which appeared at Edinburgh in 1847, even bore his name. In 1845 he left Germany for Edinburgh, after two years' stay in which city he went to London, where he became a Fellow of the Royal Geographical Society. He wrote many valuable articles on the Progress of Geography, in the *Athenæum* and the "Encyclopædia Britannica," published the "Atlas of Physical Geography" in conjunction with the Rev. Thomas Milner, and a *Tableau* of Central Africa according to the most recent explorations. It was greatly due to his influence that the English Government entrusted to the German travellers Barth, Overweg, and Vogel, missions fruitful in results both to science and commerce. Petermann also, as our readers know, paid great attention to questions connected with the Arctic regions, though his opinions on certain points connected with Arctic geography are not likely to be confirmed. Still he did excellent service in this department by advocating the equipment of expeditions private and governmental, and by recording speedily and accurately the results from time to time obtained. In 1854, Petermann accepted the chair of geography in the University of Gotha, and in 1855 received from the University of Gottingen the degree of Ph.D. It was at this time that he undertook the direction of the great geographical establishment of Justus Perthes, of Gotha, and commenced to edit the well known *Mittheilungen*, the monthly geographical review, whose scientific value has been long recognised. Petermann had a comprehensive idea of what is included under geographical science, and it will be difficult to supply his place either as editor of the *Mittheilungen*, or in the department of scientific geography.

MR. CROSS on Monday received a very numerous deputation from the British Medical Association, who laid before him their views with regard to the Vivisection Bill now before Parliament. These opinions were conveyed by Mr. Ernest Hart, Mr. John Simon, Dr. Wilks, senior physician of Guy's Hospital, and Sir W. Jenner, who raised his voice against a measure which would place men of science under police supervision, and would lay a ban upon them for inflicting cruelties on the lower animals when ten thousand times greater cruelties were inflicted by those who were going to pass this Bill. Such conduct would make those who passed it objects of scorn to all the scientific men in Europe. The Home Secretary, in reply, pointed out that the Bill was framed practically in accordance with the views of the Royal Commission, and that whether the Bill passed now depended entirely upon the line of conduct pursued by the medical profession.

WE are compelled by a pressure on our space to postpone the continuation of Dr. Richardson's articles till next week.

THE Kew museums have recently acquired some interesting additions to their already unique and valuable collections by the presentation, by his Royal Highness the Prince of Wales, of the botanical specimens collected during his recent visit to India. These specimens consist of a number of seeds and fruits of economic or medicinal value, as well as of condiments, drugs, gums, &c., from Southern India, and a series of named woods from Kanara. Though most of the seeds, fruits, and gums are already contained

in the Kew collection, so rich is it in Indian and Colonial products, some are nevertheless absolutely new, and many of them are fresher than those which have been contained in the Museum for some years.

M. RAFFRAY, we learn from *L'Explorateur*, entrusted with a scientific mission by the French Minister of Public Instruction, proposes to explore the Sunda Islands and New Guinea, especially in relation to their natural history. He takes with him as assistant, M. Maurice Maindrow, of the Entomological Laboratory of the Paris Museum. The explorers will embark at Toulon on the 20th inst. for Singapore, in a government vessel. From Singapore, M. Raffray will proceed by Batavia to Ternate and the island of Waigiou, where the two explorers intend to sojourn till the spring of next year. Proceeding then to Dorey, they will endeavour to land on the coast of the Aropin country, on the south of Geelvincks Bay, a region which has not been visited by the Italian explorers, Beccari and D'Albertis. M. Raffray expects his expedition to last for two or three years, according to the state of his health.

SIGNOR D'ALBERTIS and party have left Somerset on their way to New Guinea; they have a steam launch with them.

MR. ERNEST GILES, the Australian explorer, was last heard of at Mount Murchison on April 10, when all was well. Mr. Giles expected to reach Beltana, South Australia, about September.

IN reference to our article on the Tasmanians last week, we learn that that people are not quite extinct, though nearly so. It appears by a letter from M. Castelnau, French Consul at Sydney, to the Geographical Society of Paris, read at its last sitting, that the only four Tasmanians living were presented at the last levée held by the Governor of Tasmania. The *Times* of last Thursday intimated the death of another last Tasmanian; but evidently we have not yet seen the end of them.

WE are glad to see that the subscription for the proposed memorial to the late Mr. Daniel Hanbury is progressing; there is already a considerable list of subscribers, but there is room for many more. The memorial, as we have already intimated, is to be a gold medal, to be awarded for high excellence in the prosecution or promotion of original research in the natural history and chemistry of drugs. Subscriptions should be sent to the hon. secretaries to the fund, 17, Bloomsbury Square, W.C.

A MEETING has been held to promote a memorial to the late Dr. Parkes, F.R.S. It is hoped that a sufficient sum of money may be collected to establish a museum and laboratory of hygiene similar to those now existing at Netley.

THE Council of the Royal School of Mines have awarded the Royal Scholarships for first-year students to T. E. Holgate and F. G. Mills; the Royal Scholarship for second-year students to A. N. Pearson; the De la Beche Medal and Prize for Mining to H. Louis; the Murchison Medal and Prize for Geology, and the Edward Forbes Medal and Prize for Natural History and Palæontology, to W. Hewitt. The following have obtained the Associateship of the school during the past session (1875-76):—W. Hewitt, C. V. Boys, J. de Goncer, F. E. Lott, H. Louis, E. F. Pittman, E. B. Pressland, J. H. Barry, A. J. Campbell, P. de Ferrari, M. H. Gray, H. Gunn, W. Howard, A. B. Kitchener, W. F. Ward.

CAPT. MOUCHEZ sent to Amsterdam and St. Paul Island, some time since, a trading-vessel, in order to collect specimens of natural history to complete the collections made during the Transit of Venus expedition. The ship was wrecked on Amsterdam Island, and the crew were drowned, the captain only being saved. He remained for two months on the island, and was rescued by a Norwegian whaler. But during his forced stay in that solitude, Capt. Herman did not lose sight of the objects of his mission, and devoted to it all the time he was not obliged to devote to obtain food and shelter. All the objects collected under such peculiar circumstances have been sent to France by the Messageries Nationales, and are expected to arrive by their next steamer.

MR. FLOYD (not Lloyd), the President of the Board of Trustees for the Lick Donation, has come to an arrangement with M. Leverrier for the better execution of the contemplated instruments for the Paris and San Francisco Observatories. The masses of glass required are to be made in Paris, at Feil's glassworks, and the object-glasses very likely by an English optician. The French refractor is to have a double set of object-glasses, the necessary money having been given to M. Leverrier by M. Bishofsheim, one of the richest Parisian bankers, the donor of the Bishofsheim transit instrument now constructing at the Paris Observatory.

THE following are the numbers of visitors to the Loan Collection of Scientific Apparatus during the week ending July 8:—Monday, 3,211; Tuesday, 2,544; Wednesday, 607; Thursday, 609; Friday, 614; Saturday, 4,354; total, 11,939.

DURING the present week twelve demonstrations of apparatus were given at the Loan Collection on Monday, eleven on Tuesday, six on Wednesday, seven to-day; five will be given to-morrow, and seven on Saturday.

AN examination will begin on Tuesday, October 10, at Merton College, Oxford, for the purpose of electing to one Physical Science Postmastership, of the annual value of 80*l*., tenable for five years from election. The subjects of examination will be Chemistry and Physics. There will be a practical examination in Chemistry. Further information may be obtained from the tutor in Physical Science.

MR. THOMAS STEVENSON writes with reference to Mr. Kinahan's letter on sand-drift in NATURE, vol. xiv., p. 191, that from a passage in his book on "The Design and Construction of Harbours," second edition, p. 243, it will be learned that the pine planted by Lord Palmerston was the *Pinus maritima major*. In his report to Lord Palmerston in 1839, Mr. R. Stevenson recommended that this pine should be procured from France. A kind of bent grass was planted on the side next the sea, so as to act as a protection to the pines during their first growth. The result of the experiment was highly successful.

A REPORT has gone the round of the papers that the Government have recently made an offer to the Council of the Zoological Society of a strip of ground on the north bank of the Regent's Canal, on condition that the Gardens should be opened free to the public on one day in each week, and that this offer has been declined. This report is quite unfounded, the strip of land referred to having been granted to the Society in 1869. Upon it is built an aviary and the lodge in connection with the Primrose Hill gate. That a still further extension of the Gardens would be to the public gain, all visitors will no doubt testify.

HERR CARL HAGENBECK, the well-known dealer in living animals at Hamburg, has just received a large collection from Upper Nubia, amongst which are four elephants, five giraffes, and several other large mammalia. They are under the care of four Hamran Arabs, whose sword-hunting feats have been so well described by Sir Samuel Baker in his work on the Nile and its tributaries. Dressed in their native costumes and mounted on four fleet dromedaries, these Arabs cause quite a sensation among the inhabitants of Hamburg, and are of themselves, independent of the animals, well worthy of a visit from all passing in that direction.

THE living gorilla, which we referred to a fortnight ago as being at Liverpool, after travelling from Hull to Hamburg, was forwarded to Berlin, in the Aquarium of which city we believe it is to be deposited.

Mr. W. S. Ward, of the United States Executive, is now on a visit to England to make himself acquainted with the principles and construction of the most important public aquaria in this country with reference to the establishment of similar institutions on an extensive scale in New York, and other leading American cities.

Prof. H. G. Seeley has been appointed to the Professorship of Geography in King's College, London.

The Dutch Society of Sciences, Haarlem, has awarded the Boerhaave Medal to Prof. W. Hofmeister, Professor of Botany in the University of Lubingen.

We are doing a good deal, says the *Gardeners' Chronicle*, to bring scientific literature within the reach of the people, but our French neighbours are certainly ahead of us in this respect. This conviction is forced upon us by the recent purchase of a Manual of Botany of sixty-two pages for the sum of 10 centimes —a penny in English money! This closely printed little work, by one M. Anciaux, forms one of a series of similar *brochures* which is issued by M. Ad. Rion under the title of "Les Bons Livres." It contains chapters on vegetable anatomy and physiology, on botanical geography, classification, and taxonomy, and is certainly a marvel of cheapness.

M. Cezanne, the young and promising member of the French Chamber of Deputies for Hautes-Alpes has died of consumption. M. Cezanne, the author of a valuable work on the physical phenomena presented by waterfalls on mountains, was the founder and president of the French Alpine Club. His loss will be so much more heavily felt that the French Minister of Public Instruction is at present making great efforts to popularise the new institution. An official circular, published almost on the very day when M. Cezanne died, recommends the heads of the several government schools in France to organise tourists' expeditions during hot days for exploring the Alps and Pyrenees. Railway companies are to issue special tickets at exceedingly moderate rates.

The Prefect of the Seine Department has created a fund of 11,000 francs for sending to Dieppe, the seaport nearest to Paris, a number of pupils of the municipal free schools. Fifty will be selected from each school, and are to be chosen according to their merits. These tourist-laureates are to be boarded in the Dieppe College, visit surrounding places, and receive instruction in the natural curiosities or historical facts connected with the localities.

We observe from the *Bulletin Mensuel* of the Observatory of Montsouris for May that the Administration of Paris on April 11 last decided that meteorological observations be made with special reference to health in different parts of the city, and voted an annual grant of 12,000 francs to the Observatory, to which the inquiry has been entrusted. It has been resolved that the work shall embrace, in addition to the meteorological observations usually made, atmospheric electricity, and variations in the composition of the air (see ante, p. 156). In the meantime observations and experiments are being conducted at Montsouris with the view of arriving at simple practical methods of observing with scientific precision the different variable elements contained in the air, before extending the observations to the different quarters of the city. This number of the *Bulletin* details some very interesting results of elaborate observations made on the ozone, carbonic acid, and organic matters of the air of Paris, illustrated with figures of some of the more interesting organisms.

The interesting address by the senior vice-president, Mr. J. Thackray Bunce, at the last annual meeting of the members of the Birmingham Midland Institute, has been printed in a separate form. Mr. Bunce contrasts the condition of Birmingham with regard to education twenty-three years ago, when the Institute was founded, with its condition now. The contrast is very great indeed, and the Institute has no doubt done much to dispel the darkness in the midst of which it started. Mr. Bunce sketches the progress of the Institute, which is now in a most flourishing condition, and rightly urges the members to renewed efforts to make it increasingly useful.

The following additions have been made to the Royal Aquarium, Westminster, during the past week:—Picked Dogfish (*Acanthias vulgaris*); Bass (*Labrax lupus*); Streaked Gurnards (*Trigla lineata*); Sapphirine Gurnards (*Trigla hirundo*); Turbot (*Rhombus maximus*); Greater Pipefish (*Syngnathus acus*); Cornish Suckers (*Lepidogaster cornubiensis*); White Bream (*Abramis blicca*); Pope or Ruff (*Acerina vulgaris*); Zoophytes (*Alcyonium digitatum*).

The additions to the Zoological Society's Gardens during the past week include a Great-headed Maleo (*Megacephalon maleo*), from Celebes; a Bornean Fireback Pheasant (*Euplocamus nobilis*); two Common Crowned Pigeons (*Goura coronata*), from New Guinea; two Black-backed Geese (*Sarcidiornis melanota*), from India (?); a Saddle-billed Stork (*Xenorhynchus senegalensis*), from West Africa, purchased.

SOCIETIES AND ACADEMIES

London

Anthropological Institute, June 13.—Col. A. Lane Fox, F.R.S., president, in the chair.—Prof. Busk, F.R.S., described a collection of crania of natives of the New Hebrides, some of which had been sent to the president by Mrs. Goodenough, and others to the Royal College of Surgeons, by Dr. Corrie, R.N. Seven were from the Island of Mallicollo and three from that of Vanikoro. With respect to the former, he remarked that they were of special interest as being the first, so far as he was aware, that had ever been brought to Europe from that locality, and also from their extraordinary form, due to the artificial depression of the forehead, a mode of deformation not hitherto recorded among the Melanesian race of New Guinea and the South Sea. The peculiar form of the head among the Mallicollese was noticed by Captain Cook and the two Forsters on the occasion of the discovery of the Island in 1774. The skulls from Vanikoro, on the other hand, represented the normal form of the cranium in people of the same race.—A paper by Mr. Ranken on the South Sea Islanders, was read by Mr. Brabrook. The author proposed that the name Mahori should be adopted to distinguish the light races of the Pacific from the Papuans or blacks. He adduced evidence to show that the latter first occupied a considerable number of the islands, and that the lighter race arrived subsequently from the west and formed a settlement in Samoa, whence it is now well established, that they spread in all directions, and, in some instances, mingled with the Papuans. He mentioned several points in which the Mahoris differ essentially from the Malays, who, however, appear to be a cognate race.—A short account of a visit paid to New Guinea, by M. d'Albertis, was communicated by Mr. Franks.—Mr. Distant described some photographs of natives of the Nicobar Islands.

Geologists' Association, June 2.—Mr. Wm. Carruthers, F.R.S., in the chair.—Notes on the geology of Lewisham, by Mr. H. J. Johnston Travis, F.G.S. The author, after briefly alluding to that portion of the Upper Chalk which is exhibited in the excavations, proceeded to describe the Thanet Sands, and to compare this section with the neighbouring one at Charlton, where, in the Thanet Sands, casts of *Cyprina* and the vertebra of fish have recently been discovered. Referring to the well-known green-coated flints about which there has been so much controversy, he mentioned a circumstance which may be noted at the fault near St. John's Station, Lewisham. The Chalk and Thanet Sands are there faulted against each other at an angle of 40°, but the actual line of contact is now occupied by a band of flint. This shows that the chalk has been dissolved away by acidulous waters, following the fissure down to this band of flint, which has resisted further action. Portions of the same flint, where yet imbedded in the chalk, retain the usual white surface, whilst those portions projecting into the sands are green-coated. The author then instituted a close comparison between the Woolwich and Reading beds of the Lewisham and Charlton sections respectively.

Victoria (Philosophical) Institute, July 3.—A paper on the unseen universe, was read by the Rev. Dr. Irons.

BERLIN

German Chemical Society, June 12.—A. W. Hofmann, president, in the chair.—F. Sonnenschein spoke on two active principles of gelsonia sempervirens; one called gelsinic acid by Wormsley proved to be æsculine; the other, a strong but amorphous base, of which no compound seems to crystallise excepting perhaps the platinum-salt, acts like strychnine and digitaline and gives a red colour with sulphate of sesquioxide of cerium.—A. Müller reported on the ground water of Gennevilliers, the irrigation-ground of Paris, his analyses yielding less favourable results than those published in the reports of the Paris Commission. The President remarked upon the difficulty of drawing conclusions from isolated analyses, a continuation of systematical researches being absolutely necessary for the purpose.—C. J. Austen described a new dibromo-dinitro-benzol fusing at 99°. With ammonia it yields monobromo-dinitraniline. With aniline a corresponding compound originates, which yields a nitro-product capable of uniting with alkalies.—Emil Fischer and Otto Fischer have made new researches on the di-azo compounds of rosaniline, of leukaniline and of hydrocyano-rosaniline. The di-azoleukaniline yielded, with sodium, a hydrocarbon, $C_{20}H_{18}$ (corresponding to leukaniline, $C_{20}H_{16}[NH_2]_3$) fusing at 58°, distilling above 300°, and yielding, with chromic acid, a ketone, $C_{20}H_{16}O$.—Emil Fischer has combined phenyl-hydrazine, $C_6H_5N_2H_3$, with CS_2, forming $(C_6H_5N_2H_3)_2CS_2$. This body dissolves in potash, and from the solution sulphuric acid precipitates an acid, phenyl-sulpho-carbazinic acid, $C_6H_5N_2H_2$ CS.SH, while one molecule of phenyl-hydrazine is split off. This acid is easily decomposed by heat, yielding hard and colourless prisms $(C_6H_5N_2H_2)_2CS$, diphenyl-sulphocarbazid; alkali changes it into a black colouring matter, isomeric with the above and soluble in alkali with a red colour. Phenyl-hydrazine and bromide of ethyl yield a new crystalline substance,

$$C_6H_5N_2H_2(C_2H_5)(C_2H_5Br),$$

bromide of phenyl-diethyl-hydrazonium. With oil of bitter almonds phenyl-hydrazine forms crystals of the compo[...] $C_6H_5.N_2H.CH.C_6H_5$. Isocyanate of ethyl and phenyl-[...]zine form a urea of the composition $C_6H_5N_2H_2$ - CO - NH [...] With acetic anhydride and with oxalic ether, phenylhydrazine yields products in which one atom of hydrogen is replaced by acid radicals. At last the higher homologue, toluyl-hydrazine, has been prepared, $C_7H_7N_2H_3$ in the manner formerly described for preparing phenylhydrazine.—H. Vohl claims priority for a test for sulphur in organic compounds lately described by Weith.—B. W. Gerland described several sulphates of tetroxyde of vanadium as well as metavanadic acid.—H. Grunzweig and R. Hofmann defended the existence of crystallised ultramarine against some doubts lately expressed by Buchner.—H. Landolt published elaborate researches on the specific deviation of the plane of polarisation of solutions, from which he concludes that indifferent solvents affect the values observed very considerably, so that concentrated solutions only can furnish results of any approach to exactness.—E. A. Grete described a volumetric method of determining sulphuret of carbon, xanthogenic acid, alkalies, and copper, depending on the formation of insoluble xanthogenate of copper.—V. Meyer and F. Spitzer have transformed the product of the action of PCl_5 on camphor; $C_{10}H_{15}Cl$ into crystallised ethyl-terpene, $C_{10}H_{15}-C_2H_5$.

PARIS

Academy of Sciences, June 26.—Vice-Admiral Paris in the chair.—The following papers were read:—Geometric points and envelope curves satisfying the conditions of constant product of two variable segments; generalisation of some theorems expressed in radii vectors, by M. Chasles.—Note on the development of cos. mx and sin. mx, according to powers of sin. x, by M. Yvon Villarceau.—On the maximum of possible repulsive force of the solar rays, by M. Hirn. Taking (from experiment) 0·293833 cal. to represent the heating per square metre on the earth's surface, the two pressures 0·0004157 gr. and 0·0008314 gr. are necessarily the greatest possible for a perfectly absorbing and a perfectly reflecting surface; on any hypothesis attributing phenomena of light and heat to movements of ponderable matter. If, then, a radiometric or other experiment give, for solar repulsion, a value superior to those now specified, we must conclude against a direct impulsion by light, and the idea of mass, density, &c., in light. Now Mr. Crookes has estimated the apparent repulsion at 1 gr. per sq. metre, or more than a thousand times superior to the above maximum for reflecting bodies.—New experimental considerations on Mr. Crookes's radiometer, by M. Ledieu. This refers chiefly to experiments by M. Bertin, who has a paper on the subject in the June number of *Annales de Chimie et de Physique*.—Properties common to canals, rivers, and water-pipes with uniform *régime* (first part), by M. Boileau.—M. de Saporta was elected correspondent for the Section of Botany, in room of the late M. Thuret; MM. Godron and Duval Jouve were the other candidates.—Report on a memoir of M. Felix Lucas, entitled "Calorific Vibrations of Homogeneous Bodies." The chief object proposed is to deduce from thermodynamics the principles of conductivity of heat in homogeneous bodies, enunciated by Fourier, considering heat as the result of molecular vibrations.—Exposition of a new method for resolution of numerical equations of all degrees (third part), by M. Lalanne.—On a differential radiometer, by M. de Fonvie[...].—Process for the manufacture of soda from wrack by [...]tic steeping in lye, by M. Herland.—On the catastr[...] Grand Sable (district of Salazie), Isle of Réunion, [...] Vinson. The renewal of subterranean commotions in [...] volcanic action as the cause of the catastrophe.—Ele[...] ephemerides of planet 153, Atala, by M. Bossert.—On linear differential equations of the second order, by M. Fuchs.—On the contact of surfaces of an implex with an algebraic surface, by M. Fouret.—On some experiments made with Crookes's balance, by M. Salet.—On some derivatives of normal pyrotartaric acid, by M. Reboul.—Volumetric determination of formic acid, by MM. Portes and Ruyssen.—On the arragonite observed on the surface of a meteorite, by Mr. J. Lawrence Smith. It was in the form of white incrustation, on meteoric masses found in the desert of Mexico. The matter seems to have been incrusted on the iron after fall of the latter. The mass lay in a valley between high mountains of calcareous formation, and would often be washed and covered with water during heavy rains.—On the combinations of carbons found in meteorites, by Mr. J. Lawrence Smith.—On the employment of chloride of calcium in the watering of [...]menades, and public gardens, by M. Houzeau. At [...]ste product of the manufactories of pyroligneous [...]utilised in the way referred to, and with the best results. It impregnates the soil with hygrometric matter which makes durable for a week the moisture imparted. It is healthy, always containing a good deal of chloride of iron and tarry matters; and compared with water, it realises an economy of about thirty per cent. Further, it improves streets and roads by covering them with a sort of patina or hard superficial crust, resisting both desiccation and disaggregation.—Study on the formation and growth of some galls, by M. Prillieux.—Experimental researches on the action of aniline, introduced into the blood, and into the stomach, by MM. Feltz and Ritter. This inquiry was suggested by an analysis of wines sold at Nancy, which showed that fuchsine is largely employed to heighten the colour of wine, and to mark the addition of water. Its injurious action is shown on man and on dogs.—Researches on *Cypressus pyramidalis*, by M. Hartsen.—Process of registration and reproduction of colours, of forms, and of movements, by M. Cros.

THE UNIVERSITY OF MANCHESTER[1]

II.

WE have already discussed in last week's NATURE the present position of the higher education of this country, and we shall now endeavour to point out in what respect this is deficient, and in what way this deficiency may best be remedied.

One of the most important replies called forth by the pamphlet of the Senate of Owens College is that by Prof. Huxley, and this is alluded to in the following terms in a second pamphlet drawn up by members of the Senate :—

"Prof. Huxley, while holding that the increase of universities—in the proper sense of the term—is in itself desirable, questions whether the granting of degrees is essential to the character of a university. With the true honour and highest functions of a university, associated, as these are, not with its ordinary but with its choice products—with the flower of its students as they prove themselves in university and in the general national life—the power of granting degrees and the number of degrees granted are indeed not essentially concerned. But it can at the same time hardly be denied that examinations, and the preparation for examinations, are the proper channels through which the influence of teaching is brought home to the great bulk of students at any university, and that without examinations the efficiency of its teaching cannot be tested in reference to its average pupils. It is for this reason that the degree-granting power, in Dr. Carpenter's words, 'is usually held in this country to be the essential attribute of a university.' The degree is the outward sign of a standard reached ; this test the public has a claim to demand, more especially in fields of study to which no other practical test is applicable under ordinary circumstances, and this test it will continue to demand till brands go out of fashion. and till the public is composed of competent independent appraisers of proved merit."

These words embody a powerful argument in favour of keeping to our present system. When a man styles himself M.A. of Cambridge, for instance, this denotes unquestionably a certain intellectual training and acquirement, but it implies also a certain moral, social, and even physical training. It implies that during his residence at Cambridge his character was such as to satisfy the college authorities, while his social capacities must have been developed by the numerous influences of undergraduate life. The public has surely a right to demand this outward sign of a standard reached in the case of such a man—we may therefore take it for granted that in the future of this country the degree-granting power will be retained by the higher educational institutions. This preliminary question being settled in this way we must next ask whether the present degree-giving bodies of this country are, as they stand now, doing enough for our higher education, and if not, whether they can be made to do so by a legitimate extension of their present powers ; for clearly if bodies now in existence can be made sufficient for all the purposes of a higher education it would be impolitic and unnecessary to call a new institution into existence.

Now we think it cannot be denied that the present number of graduates turned annually out by the Universities of Oxford and Cambridge bears but a small proportion to the whole population of England ; nor will this be greatly modified by adding thereto the yearly result of the University of London—England will still be found deficient in comparison with other countries. One reason for this arises from locality, for even in these days of easy locomotion the element of locality retains an influence ; and we believe it has been found that the two English Universities draw the greatest relative proportion of pupils from counties in their immediate neighbourhoods, and the same may be said of the University of London. Nor is this to be wondered at, for the connection between a student and his University does not cease when he gets his degree. He only then truly begins to form a part of the institution and to take an interest in its proceedings, and he will on this, as well as on other grounds, attach himself, if possible, to a University in his immediate neighbourhood. At present, therefore, the whole north of England may be said to be without a University. Again, it may be taken for granted that the large and influential class of men residing in the great cities of the north of England who have become wealthy through the industries of the country, do not consider that their sons have at present sufficient facilities for a higher education. They wish their sons to be graduates of a University and to retain a connection with it in after life ; nevertheless, it is only a few of them that are disposed to take advantage of the old English Universities. They probably feel that the social training at these Universities, with all its excellence, is hardly such as to fit the majority of its graduates for success in industrial occupations ; and, on the other hand, they know that their scientific training is very much below the mark. As a matter of fact, therefore, a number of men, forming a very important section of the community, do not avail themselves of these old institutions, nor will they be persuaded to do so. They want a more suitable kind of education for their sons. Such an education is furnished by the various provincial colleges which are rapidly springing up, and of which Owens College is the oldest and best known representative—but none of these institutions have the power of granting degrees.

We must therefore conclude that sufficient facilities are not afforded to the inhabitants of the north of England in respect of the higher education, and this is especially felt by comparison with the manufacturing districts of Scotland as represented by Glasgow, a city which is the seat of a well-known University with all the privileges of granting degrees.

As one means of overcoming this deficiency, affiliation with one of the older Universities has been suggested. Regarding this scheme it is only necessary to quote the words of the Owens College pamphlet embodying the views of the Senate, that "where a college has already attained to a life and a character of its own it is impossible to accommodate it to institutions of an altogether different historical growth."

There is yet, however, another alternative. Why, it may be said, should not the University of London be definitely and finally recognised as the degree-giving body for all the provincial colleges? The great objection to this arrangement is its inconsistency with the true theory of a University, and besides as a matter of fact it does not work well at the present moment.

[1] Continued from p. 226.

Before proceeding to prove this, let us make a few remarks upon the general system of examination. A great deal has been said and written against this system, as if examinations in themselves were rather to be avoided than otherwise. This, however, is surely a mistake. The University of London does not, in our opinion, err in respect of its examinations being excessive, but rather in respect of its examinations being incomplete. *A properly conducted examination system tests the power of the pupil for producing his knowledge when occasion requires.* If it be the case that the Jesuits excel in this art, so much the more credit to them, for the art of producing one's knowledge is something desirable, which ought certainly to be taught.

Now the fault we have to find with the University of London is that, at least in its junior examinations, it does not test the excellence of the manner in which a candidate produces his knowledge, and can hardly be expected to do so. The London examination is not led up to by previous class examinations, in which the knowledge-producing power of the various pupils is carefully tested and commented on. If the candidate passes in, let us say, the matriculation examination, he may get credit for the quantity of his knowledge, but none for the excellence of his method of producing it. If he fails to pass from want of this facility, nothing is said—he is simply told that his knowledge has proved insufficient. If his power of producing knowledge is to be rectified, it must be done at his college, and under the eye of his teacher, but if he has no college and no teacher, it will not be done at all. And yet the University of London, from its privilege of granting degrees, has very great power over the various provincial colleges, and not only tells them by means of its calendar what things they must teach, but also the manner in which these things are to be taught. True freedom of teaching is incompatible with this system, and unquestionably the teaching that would *pay best* in an institution absolutely bound to the University of London would be of a style prejudicial to all originality. Indeed it would be a mistake for such institutions to have at the head of their departments teachers of originality and power of research. Teaching of the kind to suit this system is incompatible with research.

But if the University of London be deficient in this respect, it is even more so in the other functions of a University. It can hardly be said to take any account of the moral, the social, or the physical training of its alumni. In fine it has the paramount power of granting degrees, but without any corresponding responsibility, for it leaves the most important parts of its graduate education to be done by other institutions, or even not to be done at all.

In this article we have endeavoured to show that an extension of the system of the present Universities is inadequate to the educational wants of the country. In a future article we shall discuss in what way these wants may, in our opinion, be most properly remedied.

THE DUTCH IN THE ARCTIC SEAS

The Dutch in the Arctic Seas. By Samuel Richard van Campen. Two vols. With Illustrations, Maps, and Appendix. Vol. I.—A Dutch Arctic Expedition and Route. (London: Trübner and Co., 1876.)

MR. VAN CAMPEN is a native of the United States, evidently of Dutch descent, and is enthusiastic on behalf of the past and future glory of his native country. The two volumes, of which the first has just been published, have been written for the express purpose of inducing the Hollanders to reassume their place in the field of Arctic exploration, which as a nation they have deserted since the last voyage of the famous Barents, now nearly 300 years ago. The prominent position which the Netherlanders once held as navigators and discoverers all the world over, is well known, and as seamen they still occupy as good a position as ever. Their addition to the list of, happily increasing, Arctic explorers would certainly be an acquisition; and we are glad to see that a movement has been commenced by the Dutch Society for the Promotion of Industry to induce the Government to enter into this matter in friendly rivalry and co-operation with other civilised countries. We hope the Society, backed by the arguments urged in Mr. van Campen's work, will be successful in their endeavours.

The work referred to—including the volume which is published and the one to come—is the expansion of two articles in the *Transatlantic Magazine.* The author endeavours to rouse the spirit of Hollanders by insisting on the glories which their nation achieved in the past, by pointing out how much yet remains to be done ere the Arctic problem be solved, by showing them what other nations are doing, and by pointing out that the Spitzbergen-Novaya-Zemlya route belongs to them by inheritance. Mr. van Campen rather boldly, but no doubt with considerable justice, compares the Dutch in the earlier days of their history to the Phœnicians, who in the pursuit of trade penetrated into the most distant parts of the earth, making many discoveries of which the record is lost. He brings our own country to the front as the "grand exemplar" in the matter of Arctic exploration, and shows that the motives which now actuate nations in the pursuit of this field of enterprise are nobler than those which led in the old days to the quest for a north-west or north-east passage. Mr. van Campen is strongly of opinion that the Dutch in these old days made many discoveries which have dropped out of sight, and that not improbably even the Franz-Josef Land of the Payer-Weyprecht Expedition was long ago discovered and some of its points named by the Dutch whalers who used to frequent these seas in great numbers. Dr. Petermann seems also to be of this opinion; and we are sure if the Dutch can make good their claim to any discoveries which have been renamed, everyone will rejoice to restore the old Dutch names.

Mr. van Campen urges many arguments in favour of Arctic Exploration, and especially in favour of its resumption by the Dutch. These arguments we need not recount here, as all our readers have been made familiar with them in connection with the expedition, which may by this time have found the secret of the Pole. The author devotes considerable space to a discussion, or rather a comparison of opinions, as to the nature of the unexplored region round the Pole. The map prefixed to this volume shows Dr. Petermann's continuation of Greenland right across to Kellet Land, somewhat N.W. from Behring Strait. We fear few geographers will agree with this conjectural Polar continent of Petermann; all that we know points to the likelihood of the undiscovered region being broken up into an archipelago. Mr. van Campen also devotes considerable space to the question of an open Polar

sea, a question which now seems to us out of date. We think, considering the object of his work, the author has made a mistake in filling up so much space with a comparison of opinions on these questions; he has done the same with the Gulf Stream and Ocean Current question, introducing large quotations from the well-known authors who have discussed it. We do not see that all this matter is quite relevant to the object for which the book has been published. The English readers, for whom the work must be meant, are already familiar with all that Mr. van Campen has brought forward, and so, we should think, are the Dutch readers who are likely to take an interest in the work. For both English and Dutch readers great compression would here have been advisable; and, indeed, we think the whole work might have been contained in one volume. All these conjectures as to the nature of the Polar region and the extent of the Gulf Stream seem to us waste of energy, as the only method of solution is to go and see. And this is what Mr. van Campen wants the Dutch to do. He also discusses the—to English readers, at least—somewhat threadbare question of routes, and with justice shows that the route for the Dutch is their old one by Spitzbergen or Novaya Zemlya. He thinks they might try either a route to the north-east by Novaya Zemlya somewhat on the traces of the Payer-Weyprecht expedition; or—and he seems to prefer this—they might make Spitzbergen a basis of operations, and with two ships establish a depôt, and by taking plenty of time, might in this way, partly by ship partly by sledge-boat, reach the Pole. Happily, however, Mr. van Campen does not hold up the Pole as the only and chief goal of Arctic exploration; he shows forcibly and fully the many great gains to science and humanity which are to be obtained by a perfectly equipped Arctic expedition. It would, we think, be fortunate both for the Dutch and for science if they could be persuaded again to occupy the field on which of old they reaped so much glory; and now that there is every likelihood of an international system of stations being established around the Polar regions, we cannot see that so important, though so small a nation, can any longer withhold itself from doing its share of the world's work in this matter. No doubt the Dutch have for long had much to do in looking after the affairs of their own household, but now there are signs that they have leisure and wealth enough to take a substantial part in cosmopolitan work. Mr. van Campen's arguments have already been brought under the notice of several prominent Dutchmen, and we think his object would be better served by the publication of a compressed Dutch edition, than it seems likely to be by this lecture read to the nation in the hearing of the English. "As certainly as the North Pole exists is it necessary to our command of the forces of nature, in the interests of mankind, that we should know in what way the ice and snow, the long nights and day, the tides and the geological formation of lands and islands about that mysterious summit of the Polar axis, react upon more favourable and fully inhabited climes. The *Alert* and *Discovery* have gone forth, then, at the call of England only, not to serve England only, but the entire world. And not less important, we may add, would prove a Dutch Arctic expedition for the service of science and mankind."

For English readers who want, in short space, to get a knowledge of the arguments in favour of Arctic exploration, of the discussion on the subject of the various routes, of an "open Polar sea," and the configuration of the unknown region, and on the question of ocean currents and the Gulf Stream, Mr. van Campen's first volume will prove useful. The second volume will, however, possess for us more of novelty and interest, as it will contain a history of Dutch Arctic enterprise. As there are no cuts in this volume, we presume Volume II. will be well supplied with illustrations and maps. We hope soon to have it before us.

OUR BOOK SHELF

Proceedings of the London Mathematical Society. Vol. VI. (London: Messrs. Hodgson, 1876.)

PROF. CAYLEY contributes to this volume several memoirs bearing on the theory of attraction. References to some of his earlier papers on the subject are given in Todhunter's "History." The titles of the present papers are "On the Potentials of Polygons and Polyhedra," "On the Potentials of the Ellipse and the Circle," "Determination of the Attraction of an Ellipsoidal Shell on an Exterior Point," "Note on a Point in the Theory of Attraction." The order of the papers will indicate the direction of growth the subject took in the author's hands. Mehler has treated of the attraction of polyhedra, but Prof. Cayley's results "are exhibited under forms which are very different from his, and which give rise to further developments of the theory." He finds general formulæ for the potentials of a cone and a shell, he then takes the case of a polyhedron or a polygon, obtains results for rectangular pyramid, rectangle, and cuboid, and verifies some of these results. The attraction of an indefinitely thin ellipsoidal shell was shown by Poisson to be in the direction of the axis of the circumscribed cone, this property was also demonstrated geometrically by Steiner. The geometrical investigation was subsequently completed by Prof. Adams so as to obtain from it the finite expression for the attraction of the shell, a result which had also been obtained analytically by Poisson. Prof. Cayley states the geometrical theorems, proves them, and obtains analytical expressions for the attraction of the shell and for the resolved attractions. The law of attraction throughout is that of the inverse square. The same writer also contributes a paper "On the Expression of the Co-ordinates of a Point of a Quartic Curve as Functions of a Parameter." This last is the development of a process of Prof. Sylvester's. Dr. Hirst's remarks on "Correlation in Space" are a mere abstract of results, a fuller statement of which is reserved for a future communication. Prof. Wolstenholme contributes a neat piece of analysis called "A New View of the Porism of the In- and circum-scribed Triangle." Prof. Sylvester contributes two interesting notes from M. Mannheim with reference to Peaucellier's cells and their application. The Rev. W. H. Laverty supplies an "Extension of Peaucellier's Theorem." Mr. Routh has a paper "On Laplace's Three Particles, with a Supplement on the Stability of Steady Motion;" Mr. Samuel Roberts contributes a paper "On a Simplified Method of obtaining the Order of Algebraical Conditions." This method is illustrated by various geometrical applications. Further papers of an analytical character are "On the Solution of Linear Differential Equations in Series," Mr. J. Hammond; "Note on some Relations between Certain Elliptic and Hyperbolic Functions," Mr. J. Griffiths; "Notes on Laplace's Coefficients," Mr. J. W. L. Glaisher. In mixed mathematics we have papers "On the Application of Hamilton's Characteristic Function to the Theory of an Optical Instrument symmetrical

about its Axis," and "On Hamilton's Characteristic Function for a Narrow Beam of Light," Prof. Clerk-Maxwell; "On the Vibrations of a Stretched Uniform Chain of Symmetrical Gyrostats," Sir W. Thomson. The President (Prof. H. J. Smith) contributes papers "On the Higher Singularities of Plane-curves" and "On the Integration of Discontinuous Functions;" Major J. R. Campbell gives an account of "The Diagonal Scale Principle applied to Angular Measurement in the Circular Slide Rule." Shorter papers are "On the Method of Reversion applied to the Transformation of Angles," Rev. C. Taylor (the basis of the communication of which an abstract only is given in the "Proceedings," the full paper being printed in the *Quarterly Journal of Mathematics*, No. 53, is a work on Conic Sections, by G. Walker, 1794); "On some Proposed Forms of Slide Rule," and "On the Mechanical Description of Equipotential Lines," Mr. G. H. Darwin; and "On the Mechanical Description of a Spheroconic" and "a Parallel Motion," by Mr. Hart.

From this enumeration of the contents of the volume before us, it will be seen that its contents range over nearly the whole domain of pure and applied mathematics.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.]

The Government "Vivisection" Bill

ALLOW me supply an omission in the paragraph in last week's NATURE which states that Mr. Cross "pointed out" to the deputation on this subject, "that the Bill was framed practically in accordance with the views of the Royal Commission." This astonishing assertion was of course contradicted at once, but the fact does not appear in the paragraph in question; and, though the discrepancy between the Royal Commission Report and the Government Bill is notorious and acknowledged on all sides, so few people read either the one or the other, that a statement to the contrary may be believed, if allowed to pass. Those who have given attention to the Blue-book in question know that while the evidence on which Legislation was recommended went beyond the facts, the Report beyond the evidence, and the recommendations beyond the Report, the Bill actually introduced by Lord Carnarvon did not so much exceed as contradict the recommendations of the Royal Commissioners. If a reasonable registration Bill in accordance with the Report of their own nominees had been framed by the Government, they would have spared themselves and others a good deal of trouble.

P. H. P. S.

The Boomerang

I OBSERVE a letter in NATURE (vol. xiii., p. 168) asking for information about the "boomerang." I have now taken the occasion of a number of the aboriginal natives of this district being here with me for a time, to make inquiries on the subject which might confirm or correct my own previous observations. The information I have gained as to the "boomerang" I now condense, preserving, however, as much as possible the language made use of by my informant. I have also seen the boomerang thrown by one of their best performers, a short account of which I will add in conclusion to this letter.

Two kinds of boomerang are made, one called "marndwullun wunkun," that is the "boomerang," as I may translate the term "wunkun," which turns round; "marndwullun" is equally applied to the returning flight of a bird as to a boomerang. The second kind of boomerang is called "tootgundy wunkun," that is the boomerang which goes straight on, "toot" meaning something "straight" or "erect."

The two boomerangs differ in their construction. The second (straight) kind being thicker, longer, and less curved than the first, I shall call, as a matter of convenience, the "marndwullun" No. 1, and the "tootgundy" No. 2.

With No. 1 there is no certainty of hitting the mark. It may come back too quickly, and may hit your own friends standing near you. In choosing a boomerang like No. 2, in preference, it will be more sure to hit the object, and will generally penetrate the mark with the point which has been held in the hand. A black fellow will prefer one of the kind No. 2, if required for fighting. That is, he can make more sure of hitting his enemy. With No. 1 he will probably miss or even injure his friends, as it is difficult to tell where it will come back to. If No. 1 strikes an object it will never return; besides, it is generally too light to do much execution. These statements, which I have recorded as nearly as possible as given to me to-day, quite confirm my own observations made during the last twenty years in Victoria, South Australia, New South Wales, the Queensland Back country, and Central Australia. In Cooper's Creek I have seen boomerangs No. 1 used by the natives to kill ducks and birds in general which fly in flocks. They seemed unable to calculate where its course would be among them, and some were hit; the boomerang and the bird both fell. I have often seen these weapons thrown but never saw one return after striking an object. If slightly touching an object in its course, such as the small limb of a tree, it might continue a curve to the ground, but no longer in the same plane as before, and the impetus would be destroyed. A third kind of boomerang is used in Central Australia, as far at least as near to the tropics about the 141st meridian (north of Sturts Desert), which I think is only used for fighting at close quarters. Speaking from memory this variety is probably about 4 or 5 feet in length and of very heavy wood. I have rarely seen them carried, but have found them concealed near to or lying in the huts of camps from which the natives had fled at my approach. Finally, I have great doubt whether any of the natives can tell beforehand whether a boomerang No. 1 will, when finished, be a good "marndwullun wunkun" or not; and it is not uncommon for an aborigine, if he finds his boomerang to return instead of going straight to its mark, to heat it in the ashes and straighten it, so that the blade lies in one plane.

It may perhaps be not uninteresting to your correspondent if I record an instance or two in which the boomerang has been used in the settlement of quarrels in this district.

I write as follows, using the first person, and as much in the words of my informant as is possible:—

"Once I had a quarrel with one of our Kurni (black fellows). I was angry and called him 'barrat-dun.'[1] He was very cross. I had word from a friend that Daly was going to fight me. I was obliged to go, or be called 'jeeragan' (coward). A number of Kurni who had quarrelled had to fight each other at the same time.

"Our friends decided we were to fight with boomerangs. Both of us had 'tootgundy wunkun.' 'Marndwullan wunkun' would be no use, it is too light, and you can't take sure aim. Our friends stood round to see which was best man, just as I have seen the 'lowan' (white men) do. Daly threw the first boomerang because I had called him 'barrat-dun.' We threw turn and turn about. You can see the boomerangs coming. I dodged them as well as I could or turned them off with the shield. They passed me like a wind. I had a shield. If you turn the boomerangs they slide off. If you stop them they either break your shield or carry it away. One 'wunkun' passed me and stuck three or four inches into a dargan tree (Box – one of the Eucalypts). When the 'wunkuns' were all thrown we went towards each other with the 'culluck;' he put down the 'bamarook' (shield against the boomerangs or spears) and took up the 'turnmung' (shield against culluck = club). We had each a 'culluck' and a 'turnmung.' We both hit and warded off as I have seen white men do with their big knives (sword). At last Billy the Bull, one of our friends, ran in and cried out, 'moondanna' (that will do, or enough). Then we stopped. We were then friends. Daly said to me, 'Why did you call me that name?' I said, 'I am sorry.' There was no more.

"A few years ago 'Barny' woke up in his camp in the night and saw 'Lamby' standing by his fire. He was frightened, and said, 'What do you want?' Lamby said, 'Only some fire.' But Barny thought he had been 'ngarrat bun' (made sick). Perhaps it was with the 'yertung,' the little leg-bone of the kangaroo. If you point that at a sleeping man and sing a song he will be sick. I don't know the song, I never heard it; it might be, perhaps, beginning, 'Yertung, yertung, goombart, goombart.'[2] If he could do this without being seen the Kurni believe

[1] Barrat = sickness or disease. The whole term implies having acquired a loathsome form of disease, for which the aborigines have to thank the whites.

[2] Goombart is the large leg-bone, and is ground down with a sharp point at each end and worn in a hole through the septum of the nose. It is believed to have magical powers.

the man would become sick and die. I have never seen it done[1]

"Soon after Barny died News went about that Lamby had killed him Then went about also 'Laywin a ngangata' (news of war) Word was sent by the dead man's relations to come and fight at some place It was near the mouth of the Nicholson River at the Lakes All the Kurni from Bairnsdale to the Snowy River came The women sate down, beat the 'possum rugs with their hands, and called the other side names for 'ngarrat bun a Kurni' (bewitching or making sick a black fellow) The two brothers of the 'poor fellow' (the term commonly used in speaking English for dead man) threw boomerangs and 'kunnin' (a straight stick pointed at each end and about 2 feet 6 inches to 3 feet in length) Lamby had a shield At last a 'kunnin' went through his right leg just above his knee He drew it out behind and threw it back. But he missed, it was too slippery with blood Then they wanted to throw spears at him, but some 'Kurni' men and women stood up before Lamby, and the fight stopped Then they were friends Lamby had two shields (turnmung), one in his hand and one on the ground before him to be ready '

The above narratives will, I think, throw some light on the use of the boomerang, and are characteristic of the customs of the aborigines, which it is much to be regretted are going to oblivion A careful record of these—in fact a faithful record of the customs, the beliefs, the systems of consanguinity of the Australian aborigines would throw much light on the probable early condition even of the now civilised races I have for some years treasured

up for future use everything I could gather on these subjects This mine of strange information is immense, and I regret to say not only unworked, but I fear destined to remain so—while the aborigines are rapidly fading away before the advancing wave of settlement To anyone who has not endeavoured to collect such information through others, the utter apathy which exists throughout the Australian colonies may seem inconceivable I regret to say that sad experience has shown me that it exists As an instance I may mention that of some 400 or 500 circulars which I have, together with my colleague in the inquiry, the Rev Mr Fison, sent out asking for information as to the systems of kinship obtaining, certainly not five per cent have produced replies, and scarcely more than one per cent yielded results.

This is, however, a digression, and I now give, as illustrating the two above narratives, slight sketches of the "bamarook," the "turnmung," and the "culluck

The boomerang throwing to which I have referred took place on the open flat lying between the River Mitchell and its branch known as the Backwater It was open and well suited for the purpose, but a sea-breeze was blowing There were present eight black fellows from different localities, extending from the Mitchell River to the Snowy River Among them was Lamby, the hero of the fight which I have narrated, Toolabar, a brother of the man Barny, and Long Harry, the acknowledged boomerang-thrower of the whole district, so much so that when I suggested that he should be called for the future "Bungil Wunkun," *i e*, "He of the Boomerang," the term was received with acclamation, and it is not improbable that for the future this may be his native name The only boomerang we had was one of the "marndwullun," or returning sort Throws were made by all, and the defects of the throws as well as of the instrument pointed out by one or the other almost in the same terms One arm of the boomerang was held to be too much curved for the instrument to return near the thrower. The throws proved this to be the case, as it was evidently impossible for the thrower or the spectators to tell exactly what the course of the missile would be in returning In some case it flew past over our heads and fell in the rear, at others flew in the opposite direction far to the front The explanation of this given me was that it was partly due to the uncertainty of the boomerang's return flight unless of rare perfection in make, and partly due to the wind which affected its course I found that the throws could be placed in two classes, one in which the boomerang was held when thrown in a plane perpendicular to the horizon, the other in which one plane of the boomerang was inclined to the left of the thrower

In the first method of throwing, the missile proceeded, revolving with great velocity, in a perpendicular plane for say 100 yards, when it became inclined to the left, travelling from right to left It then circled upwards, the plane in which it revolved in [illegible] a cone, the apex of which would lie some distance in front of the thrower. When the boomerang in travelling passed round to a point above and somewhat to the right of the thrower, and perhaps 100 feet above the ground, it appeared to become stationary for a moment, I can only use the term *hovering* to describe it It then commenced to descend, still revolving in the same direction, but the curve followed was reversed, the boomerang travelling from left to right, and the speed rapidly increasing, it flew into the rear At high speed a sharp whistling noise could be heard In the second method, which was shown by "bungil wunkun," and elicited admiring ejaculations of "ko ki" from the black fellows, the boomerang was thrown in a plane considerably inclined to the left It then flew forward for say the same distance as before, gradually curving upwards, when it seemed to "soar up—this is the best term—just as a bird may be seen to circle upwards with extended wings The boomerang of course was all this time revolving rapidly It is difficult to estimate the height to which it soared, making I think two gyrations, but judging from the height of neighbouring trees on the river bank, which it surmounted, it may have reached 150 feet It then soared round and round in a decreasing spiral and fell about 100 yards in front of the thrower This was performed several times The descending curve passed the thrower I think, three times Other throws were spoiled by the wind, which carried the boomerang far to the front I observed, and some of the aborigines confirmed it, that the thrower preferred throwing with the wind Another method of throwing was mentioned, namely, to throw the boomerang in such a manner that it would strike the ground with its flat side some distance in front of the thrower It would then rise upwards in a spiral, returning in the same. This was not attempted as it was decided the boomerang was not strong enough. A final throw in a vertical plane so that the missile struck the ground violently fifty or sixty yards in advance terminated the display It ricocheted three times with a twanging noise and split along the centre My black friends said they should soon manufacture a number of the best constructed "wunkun" to show me I observed that the spectators stood about a hundred yards on one side of the thrower, and when the boomerang in its gyrations approached us every blackfellow had his eyes sharply fixed on it The fact stated by them that it was dangerous was well shown in one instance, where it suddenly wheeled and flew so close over us that I and Toolabar fell over

[1] As an example I may give the snake charm which is sung to a monotonous chant. The blacks tell me they sing this and suck the wound for snake bite —

"Yane thay, gaylunga gaylunga
Yane thay, gaylunga gaylunga
Willel a wirreba, wirn biyow

repeated indefinitely It may be translated —

'Oh, the jaw of the gaylung, the gaylung
Oh the jaw of the gaylung the gaylung
Go and hide yourself in the bush in its nest

Gaylung is I believe, a Hoplocephalus and very deadly It is said to frequent the rats nests, which are made of grass

each other in dodging it. The expression used by them was "Marndwullun no good for fight; if he no hit 'em man, might come back and hit your friend beside you." I questioned the black fellows as to whether they thought a boomerang could be thrown so as to return to the hand of the thrower. Seven said "no," and characterised the statement as "jetbollan," *i.e.* a falsehood; the eighth said he once made a boomerang that when thrown on a calm day with great care would gyrate round and round until it descended to the ground not far from him, moving as slowly as a leaf falling from a tree, and that he once ran forward and nearly caught it. He said also "no Kurni (black fellow) can catch a wunkun when he flying—he would cut his hand open."

All the black fellows were unanimous in stating that a boomerang when it has struck anything ceases its course.

I have now stated all that at present suggests itself as to the boomerang. I fear that I may have trespassed too much on your space and on the patience of your readers.

Bairnsdale, Gippsland, Victoria, March 3 ALFRED W. HOWITT

Fertilisation of Flowers.—The Cuckoo

As a fact interesting in connection with the fertilisation of flowers, I have observed that in *Scabiosa arvensis* the stamens are elongated and the anthers ripened successively—not simultaneously—in each individual floret, the first having fallen off the filament, while the fourth is yet colourless and curled up in the tube of the corolla, the other two being in intermediate stages of development.

May I also state in reference to the Cuckoo, that a rhyme well known in Somersetshire, runs thus:—

"In April, come he will,
In May, he sings all day,
In June, he alters his tune,
In July, he prepares to fly,
In August, go he must."

By which it is clearly not meant that the Cuckoo ceases to sing in that part of the country at Midsummer. This break of note in June is generally to be noticed about the middle of the month. I, this year, heard it for the first time on the 28th May.

Ealing CHAS. FRED. WHITE

The Cuckoo

IN connection with the notes of Mr. Adair and Mr. Joyner in NATURE of July 6th and 13th, let me record that the Cuckoo has not even yet left us in the Midlands. I heard it only last evening near to my own house. There is a popular rhyme, long current in Derbyshire, concerning this bird. One couplet tells us the Cuckoo may be heard

"In April, May, June, and July,
If she sings any longer she'll tell a story;"

so that even this rude rhyme shows that it is not expected to depart earlier than this month. LLEWELLYNN JEWITT

ABSTRACT REPORT TO "NATURE" ON EXPERIMENTATION ON ANIMALS FOR THE ADVANCE OF PRACTICAL MEDICINE[1]

IV.

Experimentation for Determining the best means of Restoring Animation after some Forms of Accidental Death.

THE frequent occurrences of death from the administration of chloroform and other agents of the anæsthetic series led me very early to experiment for the purpose of discovering the best means of restoring life after such accidents. I commenced this research in 1851, and have continued it up to the present time. I consider it to have been one of the most fruitful in useful practical results. The details of the work have been communicated at various times to the world of science, and at considerable length. They formed the subject of a special report to the British Medical Association at its meeting in London in 1862. They formed the subject of a report to the Royal Society in 1865. They were continued in the Croonian Lecture delivered before the same Society in 1873, and they were introduced into various lectures on experimental and practical medicine, and into reports on the physiological action of organic chemical compounds made to the British Association for the Advancement of Science.

[1] Continued from p. 199.

As the account of these inquiries covers a great deal of ground and brings into light many curious and interesting topics, I shall devote a little extra time to the abstract of the experimentation.

Method of Experimental Research.

The mode of experiment in this research has consisted chiefly in testing the action of the narcotic vapours; the vapours of chloroform, ether, nitrous oxide, carbonic acid, choke damp, carbonic oxide, hydrocyanic acid, methylal, chloral hydrate, and others similar. Some inquiries have also been made relative to instant death by mechanical and electrical shocks, and to death by drowning and cold.

In every case the animal has been submitted as painlessly and rapidly as possible to the process which we call death. The rapidity and painlessness were essential to the experimental inquiry; because the more rapidly and the more placidly the animation is suspended, the less is the body exposed to the risk of organic injury.

In the course of observation two steps have been followed.

I.

In the first line of inquiry the animals have been allowed to die without any attempt to restore life, the object being to ascertain why death took place. After death the organs of the body have been examined in order to determine what was the action of the destroying agent on them. How did it arrest the living action?

The first question asked had relation to the condition of the lungs:—Were they left bloodless, containing some blood, or congested with blood? The second question had relation to the heart:—Were its cavities left full, or empty of blood; were they distended or collapsed; was the blood left in the cavities of natural or unnatural colour; were the muscular walls of the heart still excitable to motion, or were they quite inactive; if the muscular walls were inactive were they rendered inactive by rigidity of contraction or by relaxation? The third question had relation to the blood:—Had the blood undergone coagulation, and if it had not at the time when the examination was made, how long a time elapsed for the completion of the process? What was the condition of the blood corpuscles; were they scattered or massed together, were they perfect in outline or irregular? What was the colour of the blood on the two sides of the circulation; was the venous blood darker than the arterial, or were the two kinds of blood mixed in respect to colour? Were any gases escaping from the blood or had any escaped? Had the fibrine escaped from the other constituent parts? Had the blood accumulated in any of the vascular organs, or had it exuded from its vessels in whole or in part? The fourth question related to the state of the nervous organs, the brain and spinal cord:—Were these organs congested or free of congestion? Was there any effusion of blood or of serum into them? Was the appearance of the white and grey matter natural or morbid? Were the membranes vascular or pale? The sixth question had relation to the state of the visceral organs in the cavity of the abdomen:—Were the kidneys free of congestion, or were they congested? Was the colour of the intestines natural? Were the liver and spleen congested or free of congestion? The seventh question had regard to the muscular system:—How long a period elapsed before the muscles became spontaneously rigid? After what modes of death from the different agents did the muscles continue most active under the influence of the galvanic current? What sets of muscles first ceased to respond to the current, the muscles of respiration or the muscles of

locomotion? What other stimulants than galvanism would excite muscular movement after systemic death?

The above-named questions follow in series in relation to the condition of the animal body and its parts after death. In addition other observations were made to which it is necessary to refer.

The influence of the narcotics on the temperature of the body immediately before and after death was studied with much care. The variations of the animal temperatures under different degrees of natural atmospheric temperatures, from summer heat to extreme of winter cold, were noted. The different modifications of temperature that occurred in different organs of the body, brain, stomach, lungs, heart, liver, and abdominal cavity immediately after death were also observed.

The influence of the anæsthetic vapours on the minute or capillary circulation of the blood was determined by microscopical observation. In these experiments the web of the foot of the frog was made the field of observation. The animals were narcotised with the different vapours, and while narcotised the state of the circulation through the minute vessels, arterial and venous, was recorded during every stage of narcotism, and was compared with the state of the same parts that existed previous to the induction of the narcotic condition. The information sought for in this part of the inquiry related to the action of the narcotic vapour on the circulation of the blood corpuscles through the minute vessels; the changes of form in the corpuscles, red and white, if any changes occurred in them; the changes in the calibre of the vessels on the arterial and venous side; the point of arrest of the circulation through the vessels when the circulation finally stopped; the point of return of motion if the circulation were restored; and, the effect of various changes of external conditions such as warmth, cold, and moisture on the circulation during the stages of narcotic sleep.

One other important part of this line of inquiry was the determination of the conditions in which an animal body assumed to be dead could be best kept so as to retain those states of organs and parts which are favourable to the re-establishment of living motion. Should the body be left in a warm or a cold atmosphere? What circumstances determine the suspension of the process of coagulation of the blood and of cadaveric rigidity? Briefly stated these were the points of inquiry sought for under the first direction of research. By them I have been able to distinguish the conditions in which all the known anæsthetics leave the organs of the body when they kill.

II.

In the second line of inquiry the objects sought after were the rational means, suggested by the previous inquiries, for recalling animation after the signs of life have ceased. In this direction the following questions were asked:—

1. What is the precise value of *artificial respiration?* What is the most perfect method of carrying out artificial respiration? How long should the process of artificial respiration be continued, and what are the proofs that its continuance will be useless? When it has proved useful in restoring natural respiration, how long should it be continued? What dangers are connected with its employment?

2. Is it possible when the phenomena of suspended animation are present, to restore the circulation? By this process, to which I have given the name of *artificial circulation* (*British and Foreign Medico-Chirurgical Review*, April, 1863), I tried to restore the current of blood through the vessels, by transfusion of other blood; by mechanically pumping the blood within the veins of the dead body, over the lungs into the arterial circuit; by attempting to draw the blood over into the arterial circuit from the venous circuit; by altering the position of the body in alternate motion up and down.

3. Is it possible to combine artificial respiration with artificial circulation? In this endeavour I tried the combination of the two methods, and with the hope of being able to drive or draw a current of blood over the lungs while the blood remained fluid, and of being able also to aërate the blood in its passage by keeping up artificial respiration.

4. Is it possible to utilise the galvanic current so as to restore animation? In this inquiry the galvanic current was employed so as to call into play the action of the muscles of respiration: the heart: the voluntary muscles.

5. Can the heart, after it has stopped, be excited into motion by injecting into it agents which stimulate it to contraction? In this inquiry ammonia and other excitants were injected into the heart, while artificial respiration was maintained.

6. What is the value of external warmth in various degrees for restoring animation? In this research the effects of warm external applications, warm sand, moist warm air, dry warm air, moist warm straw, and other similar means were carefully tested.

In the briefest terms I have thus sketched out the mode of inquiry adopted in the course of experimentation now under notice. Fuller details are recorded in the paper published in 1863 in the *Medico-Chirurgical Review*, but these now given are sufficient for this abstract.

RESULTS.

The practical results which have followed on these researches are very numerous. I will write those which seem to be most practical and useful.

On Artificial Respiration.—In respect to artificial respiration the following facts were learned:—

If artificial respiration be sustained, even with an atmosphere of chloroform that is sufficiently narcotic to keep up deep narcotism, the action of the heart continues and recovery of life is possible. In brief, the mode of death from chloroform and perhaps from all the other narcotic vapours is actually due to the arrest of the current of blood through the minute vessels in the circuit of the lungs.

Artificial respiration, when perfectly carried out, was found sufficient to restore life after natural respiration had entirely ceased, and when all external evidence of motion of the heart had also ceased. To make this fact matter of direct application, I invented a double-acting elastic hand-bellows, which performed when in action the double purpose of emptying the lungs of their contained air by one movement, and of filling them with fresh atmospheric air by another movement. I also arranged the instrument in such manner, that on emptying the lungs of air a current of blood is mechanically drawn upwards from the right side of the heart, by which the oppression of the right side of the heart from tension is removed, and its muscular contraction is recalled into play. My latest instrument for this purpose is now so graduated, that measured quantities of air can be withdrawn and introduced, and the physico-chemical action of the lungs can be imitated with the greatest refinement, and with results that are different to any that have been gained before. Thus, after death from some of the narcotic vapours I have been able to restore life as long as eleven minutes after all the external signs of life have ceased. The results of the experiments proved also that when once the natural respiration is established the artificial ought to cease, so that the enfeebled circulation and respiration may return into play together. Further, the experimentation showed that artificial respiration, while it may be made, by delicate using, an all but certain means for the restoration of life after death from narcotic vapours, it may by bad use be made the certain means of ensuring death; that in performing it any rude movement of the body, or any violent inflation of the lung, or any attempt to inflate the lung while the lung is full of air, and the right side of the heart, full of blood, is sufficient to complete the process of destruction of balance and to cause unavoidable death. In a word, the experimentation

showed that as with a fire that is well-nigh burned out we can restore action by laying new fuel lightly on the remaining flame, and then by gentle blowing can communicate the flame to the new fuel, so in artificial respiration the same delicacy of procedure will reproduce the vital flame.

In the absence of experimentation these facts could never have been learned. It was necessary to see the effects of various methods under various conditions, and under various circumstances in order to arrive at certain conclusions. A century of observations on men subjected to accidents that destroy life would not have taught so much as was learned in a few hours from the observations on the inferior animals.

Artificial Circulation.—The inquiry on the subject of artificial circulation proved that the attempt to establish the circulation by injection into the vessels, or by forcing the blood over the lungs, or by drawing it over in combination with artificial respiration, failed by reason of the coagulation of blood which followed such attempts. Some countenance was given, by the experiments, to the attempt to encourage a current of circulation by the process of raising and depressing the body so as to place the head at one moment below the level and at another moment above the level of the body; but on the whole the effort to restore the circulation through the lungs was most expedient by the simple plan of artificial respiration carried out as above stated.

Use of Galvanism. The research instituted to test the value of galvanism as a means of restoring animation had a most important practical bearing. By regulating the intermittent current with a metronome I found it possible to make the respiratory muscles of an animal recently dead act in precise imitation of life. I also found that the heart could be excited into brisk contraction by the same means. But the result came out that by this method the muscles excited by the current dropped quickly into irrevocable death through becoming exhausted under the stimulus, and that in fact the galvanic battery, according to our present knowledge of its use in these cases, is an all but certain instrument of death. By subjecting animals to death from the vapour of chloroform in the same atmosphere, and treating one set by artificial respiration with the double-acting pump, and the other set by artificial respiration excited by galvanism, I found that the first would recover in the proportion of five out of six, the second in proportion of one out of six. Further, I found that if during the performance of mechanical artificial respiration the heart were excited by galvanism, death was all but invariable. The explanation of these experimental truths is illustrated by a simple simile. If an animal reduced in power to the last degree from want of food be carried to a place of succour, it may recover; but if it be stimulated or forced to walk to the place it will possibly die on the way. So with a man or animal under prostration from shock or narcotism; if the surgeon uses his own force for the restoration of the enfeebled muscles of the man before him he may restore the muscles to power; but if he uses up the last remaining force in the muscles of his patient by stimulation he will kill them outright. Considering that in the large number of instances of sudden death by accident, the first thing "tried" for restoring life is the galvanic battery, the information on the subject thus yielded by experiment, and which could have been got in no other way, is a result which, though unexpected, is none the less valuable. Indeed the peculiarity of experimental pursuit is that something unexpected in result is always learned, and is almost always useful.

Injection of Stimulants.—The effect of injecting ammonia, and other stimulants into the heart for the purpose of exciting the walls of the heart into contraction, was found to be as faulty as the application of galvanism for the same purpose. It produced a final contraction which was fatal.

Use of External Warmth.—The research on the action of warmth on animals under suspended animation was singularly interesting. I found that when an animal under a narcotic is still breathing, however faintly, the restoration of the animal warmth is often alone sufficient to restore life. This came out of the observation of the action of narcotics in reducing temperature, and in my first researches on chloral hydrate I showed that of two animals under the same lethal dose one was safe to recover in a warm air, while the other in a cold air would die. These facts relate to animals which are still breathing though all but dead.

On the other hand, I discovered that if an animal had actually ceased to breathe, the most certain way of ensuring its death is the exposure of it to heat; the most certain way of retaining it in a condition for possible recovery and of retaining its muscular irritability under stimulus is the exposure of it to cold. Heat I found excites the final muscular contraction and causes coagulation of the fibrine of the blood; cold suspends both. Thus in a warm-blooded animal exposed, after its death from chloroform, to extreme cold in a dry air, I found every muscle in the body that I could reach vigorously active under re-applied warmth and galvanism three hours after death; while in fish and batrachians I found it possible to restore life altogether after they had been accidentally inclosed, that is to say, frozen up in ice. As we arrive at clearer knowledge of the means of restoring animation in man, these facts will have a bearing of the extremest value. Already they indicate that in the death of the human subject by drowning and cold, attempts to restore life are demanded even hours after the occurrence of the accident.

Lastly, on this head, the experimentation taught me that while in the process of resuscitation it is very bad practice to immerse the body in a heated medium like hot water, it is of the utmost importance to establish the artificial respiration with a warm and dry air. Such an air prevents condensation of water in the bronchial tubes, quickens the process of oxidation of blood, and allows the body to become warm from its own natural centres of vital heat.

PRACTICAL APPLICATIONS.

The experimental inquiry herewith briefly stated is too new to have brought forth much fruit. The grand practical results for which it was pursued have to follow in course of years. Some results have, however, already been realised.

Immediately after chloral hydrate came into use, the dangers from its use were found to be imminent. I was able to point out even before such dangers had occurred that the cause of danger was reduction of animal temperature from the agent, and that in treating a person poisoned with chloral two things were required, viz., to maintain a high atmospheric temperature, and to give warm food. Twice I have been summoned to these accidental poisonings, and in both instances I have saved life by these simple and purely scientific modes of cure. Probably after a number of deaths of men from chloral, it might have been learned that the cause of death was the reduction of animal heat. The fact gained instantly by observation on the lower animals supplied the knowledge in advance of the accident.

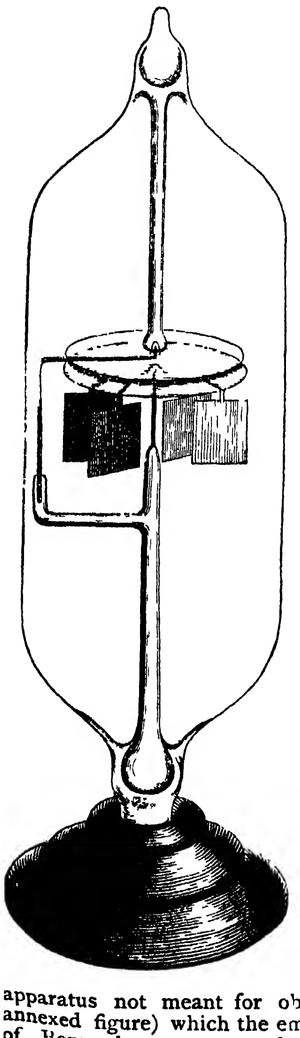
In two instances in the human subject in which after the performance of the operation of tracheotomy, life has become suspended from obstruction to the entrance of air into the lungs below the artificial opening, the obstruction has been removed, and afterwards by means of artificial respiration carried out with the instrument I have described above, life has been restored after all the ordinary evidences of death were manifested. In one of these examples of restored life the recovery was complete and the patient is now as well as ever he was. But for the long period of eleven minutes he lay in all the character of death, depending solely for returning life on the surgeon who supplemented his respiratory power and who gently fanned back into life a flame which had ceased for ever if scientific experimentation on the lower animals had not shown the possibility of its return by the hand of science.

(*To be continued*)

SCIENCE IN GERMANY

(*From a German Correspondent*)

It is known to have been first discovered theoretically by Maxwell, that the co-efficient of friction of a gas is independent of the pressure. This law has been tested and confirmed by Maxwell and O. E. Meyer, and more recently by Kundt and Warburg (*Philosophical Magazine*, 4, vol. iv.; and fully in *Poggendorff's Annalen*, Bd. 155 and 156) with reference to the sliding of gases in limits between 760 and 1 mm. pressure of mercury. The latter experimenters observed, as Maxwell did, the decrease of vibrations of a round glass disc suspended bifilarly between two fixed plates. At pressures under 1 mm. Kundt and Warburg were unable accurately to investigate the friction. They could perceive, however, that with continued progressive evacuation by the friction apparatus, the damping force exerted by the rarefied gas on the motion of the oscillating disc, decreases; still, even in the best vacuum which could be produced, it had still a considerable value. Thus, *e.g.*, in the best hydrogen vacuum which Kundt and Warburg could produce, the damping force was not less than one-third of the value obtained with full hydrogen-pressure (760 mm. mercury).



To demonstrate the friction in such a vacuum before a large audience, Prof. Kundt recently constructed an apparatus, which he employed when giving a lecture on the gas theory before a scientific society in Berlin in March last. The essential part of the apparatus consists of two small discs of mica, suspended one over the other in an evacuated space. When the under disc, which, like Crookes's radiometer, is furnished with four light vanes blackened on one side, is set in rotation by the action of light, the upper disc begins to rotate in the same direction (though much more slowly) in consequence of the friction of some traces of air still present in the apparatus. (The upper disc of course nowhere touches the lower.) The description of this apparatus with drawings, will shortly appear in *Poggendorff's Annalen*. Here we content ourselves with the representation of a smaller apparatus not meant for objective demonstration (see annexed figure) which the eminent glass-artist, Geissler, of Bonn, has constructed at the instance of Prof. Kundt. This apparatus, like the ordinary radiometer, is entirely inclosed in glass. On a fine steel point rests, by means of a cap, the lower mica disc, with the radiometer cross fixed to it. The upper disc rests likewise on a fine steel point. This point is fixed to an arm which reaches over the lower disc, but without being in contact with it. On the upper disc a small mark is made (not shown in the figure), which enables one to perceive whether the disc rotates or not. Illuminated by the sun or candles, the radiometer cross with the mica disc fastened to it, enters into quick rotation, and the upper disc begins gradually to rotate in the same direction as the lower one.

S. W.

ON MODES OF DEMONSTRATING THE ACTION OF THE MEMBRANA TYMPANI

The movements of the bones of the tympanum in connection with sound-waves were first observed and their excursions measured by Buck ("Archiv. of Ophthalmology and Otology," vol. i., 1870), and more recently by Dr. Charles H. Burnett of Philadelphia, as recorded in the same Journal for 1872. The method followed in these researches was to expose the bones and membrane by chiselling away a portion of the wall of the tympanum, sprinkling on the chain of ossicles a little powdered amylum, so as to secure bright vibrating points, throwing light into the cavity by means of a condenser, and observing, with a microscope of low power, the excursions of the vibrating points when sound was conducted into the external ear. Various interesting deductions were drawn from these experiments as regards the amplitude of the excursions of vibrating points on different portions of the conducting mechanism, and as to the effect of variations of the fluid pressure within the labyrinth on the extent of movement. In the last number of the same journal an interesting paper appears from Dr. Clarence J. Blake of Boston on "the use of the Membrana Tympani as a Phonautograph and Logograph," accompanied by a plate. Dr. Blake's method consists of exposing the membrane and chain of bones, and fixing a light style (made "by splitting long wheat straw, scraping the inner cortical substance away, and separating single fibres") to the membrane. This style is caused to record its movements on a plate of smoked glass which is "carried smoothly and at a uniform speed in a direction at a right angle to the direction of the excursion of the style." . . . "The membrana tympani being set in vibration, and the carriage [bearing the smoked glass] drawn by its weight, moving at right angles to the excursions of the style, a wave-line, corresponding to the character and pitch of the musical tone sounded into the ear, is traced on the smoked glass."

There is still a third method which I have recently devised, chiefly for class illustration. It consists in converting the tympanic cavity into a manometric capsule, according to the method of Dr. Kœnig (*Philosophical Magazine*, 1873, vol. xlv. pp. 1-18, 105-114), and of viewing the oscillations caused by sound in a revolving mirror. A preparation is easily made from the ear of the cat. After sawing out the temporal bone, clearing away all loose tissue, and exposing the tympanic bulla, I make two small holes in the latter by means of a fine trephine. Into these holes two glass tubes, of corresponding diameter, are cemented with sealing wax—the one for leading gas into the tympanic cavity, and the other out of it. The preparation (which may be preserved in a moist state in a well-stoppered jar for a long period, and be used over and over again) is firmly fixed in a vice, one tube is connected with the gas supply, and the other with one of Kœnig's small burners. By means of a third tube inserted into the external auditory meatus, sound-waves are conducted to the membrane of the drum, the mirror is rotated, and the usual pictures corresponding to the pitch and quality of the sound are seen with exquisite delicacy. I have found tones of medium pitch (ut 3 to sol 4) produce the most distinct effects, and the vowels, if uttered with sufficient intensity, produce pictures which are quite characteristic. By using a preparation in which the auditory apparatus on each side is present, it is easy to devise an arrangement for showing the effects of

interference, in a manner similar to Kœnig's well-known apparatus for that purpose, constructed on the method of Wheatstone.

JOHN G. MCKENDRICK

THE GEOLOGICAL SURVEY OF NEWFOUNDLAND

DUE no ice of the Report for 1874, of Mr. Murray, the Director of the Newfoundland Geological Survey, has been delayed until the appearance of the map and sections referred to in that Report. These we have now received, and as they deserve more than ordinary attention from geologists, we propose to give some account of the recent work of the Survey. The able and indefatigable Director, who, like his late chief, Sir William Logan, has grown grey in the service of the Dominion, divides his Report into two parts, one of which narrates his own labours during 1874, while the other is furnished by his assistant, Mr. J. P. Howley, of whose surveys for the same period it gives the main results. Mr. Murray's Report is marked by that quiet practical good sense which formed so characteristic a feature of his contributions to the Canadian Geological Survey. It is more occupied with plans and advice for opening up the country to settlers, and developing the great resources of the island in timber and as a cattle-grazing district, than with geological matters. The latter are treated, too, with an eye to future mineral industries. Mr. Murray, in short, is doing the solid and useful work of pioneering. That work may make no brilliant display at the time, but if, as he hopefully anticipates, there is a prosperous future before Newfoundland, the colonists will look back upon his labours as those which largely guided and stimulated that prosperity.

But Mr. Murray is too true a geologist to let any chance escape him of advancing the purely scientific treatment of geology. And he is fortunate in possessing in Mr. Howley a geologist who can carry out his views with admirable skill. From Mr. Howley's Report and Map geologists in other countries will learn some particulars not only important as regards the geology of the colony, but of general interest as bearing on the question of the nature and *modus operandi* of the metamorphic action to which the origin of such rocks as dolomite and serpentine is attributed.

Mr. Howley's labours during 1874 were, in accordance with Mr. Murray's plans, given to the survey, topographical and geological, of the western coast of Newfoundland, about the peninsula and bays of Port-a-Port, and St. George's Bay. In tracing the Lower Silurian formations of the Newfoundland coast, Mr. Murray and his colleagues have been able to identify them with more or less precision as equivalents of the Quebec and Birdseye and Black River groups of Canada. But in the course of their surveys they have at different times encountered intercalated sheets of metamorphic rocks in the Lower Silurian series overlying unaltered and fossiliferous strata. Thus at Bonne Bay, in 1862, Mr. Richardson found highly metamorphosed rocks, including white talcose slates and serpentine, in some portion apparently of the Quebec group. Four years afterwards Mr. Murray observed further south, in the Bay of Islands, that sandstones believed to represent the Sillery zone of the Quebec group passed below the serpentine of the Blowmedown mountains. Mr. Howley has now confirmed and extended these observations by mapping the country between the Bay of Islands and St. George's Bay. He has traced Mr. Murray's serpentine rocks southwards to Bluff Head, and finds that they pass unconformably over different horizons of rocks which are taken to represent the Sillery and Levis subdivisions of the Quebec group of the Lower Silurian system. The striking character of this unconformable junction is well brought out upon the map, where two large cakes of the overlying rocks are seen to sweep over both anticlinal and synclinal folds of the lower formations. These cakes consist of brecciated dolomite or limestone, chlorite-slate, diorite, and serpentine, having a total thickness of perhaps 1,500 feet. Their exact geological horizon seems not yet quite satisfactorily fixed, but they are placed provisionally between the Sillery and Birdseye and Black River formations. Doubtless further details will be given in future reports regarding this remarkable feature of Newfoundland geology, and till they appear it may be well to avoid any discussion of the theoretical aspect of the subject. It is not the first time that an instance has occurred of the higher rocks of a district being more metamorphosed than the lower, but there has probably never been observed so remarkable a case, for here the metamorphosed and contorted series is described as actually overlying unmetamorphosed strata.

Other questions of interest occur in the Report. Thus, a centre of pre-carboniferous volcanic action is indicated as existing along a line north of Fox Island and on the coast to the south head of the Bay of Islands. The coal-measures, of which a few patches occur in the district surveyed, overlap from the Millstone Grit on to the Carboniferous Limestone. The latter formation contains, according to Mr. Davidson, brachiopoda which all belong to well-known British species. In another respect there is a curious analogy between the base of the Carboniferous system in Newfoundland and in some parts of Britain. In the former country the lower members of that system consist largely of red and green sandstones, clays, and conglomerates, with traces of plants, beds of gypsum, and occasional limestones full of ordinary Carboniferous Limestone fossils. Anyone who has looked at the base of the Carboniferous system in Cumberland, Westmoreland, Dumfriesshire, and other parts of Britain, will recognise these lithological features as characteristic also in this country. It would seem that the same physical conditions preceded the deposition of the Carboniferous Limestone on both sides of the Atlantic inland seas or lakes, not far separated from the sea, in which red sediment with gypsum and occasionally common salt was laid down, but which were not usually well suited for the support of molluscan life, though liable now and then to inroads of the sea outside and to invasions of mollusca, corals, and other marine forms.

The map, on a scale of four miles to an inch, is evidently a piece of most careful work. It shows the arrangement of the rocks from the Laurentian group up to the Coal-measures, though, partly from vast unconformabilities and partly from faults, great portions of the geological series are not represented in this part of Newfoundland. It may be mentioned, in passing, that the largest fault traced on the map- that which flanks the Laurentian range from Table Mountain north-eastwards to Grand Pond—is not coincident with the line of any river, but is crossed by all the chief rivers and brooks in the district which it traverses. Hence the same relation between fracture and erosion exists there which has been so extensively traced and keenly discussed in this country. To the completion of this important map geologists will look forward with not less interest than must be taken by those who see in the labours of Mr. Murray and his associates one of the best pledges for the early development of the colony.

A. G.

THE ANCIENT BRITISH PIG

PROF. ROLLESTON has recently been making some researches on swine, the discovery of some remains buried in the alluvium, near Oxford, having directed his attention to the subject. In illustration of a paper "On the Prehistoric British *Sus*," read by him at the Linnean Society, June 15, the following specimens were exhibited :—1. Skull of *Sus scrofa*, var. *domesticus*, from a late Celtic interment. 2. Skulls of *Sus scrofa*, var. *ferus*, from

alluvium near Oxford, and from Germany 3. Skull of *Sus andamanensis*, forwarded him by J Wood Mason. 4 Skull of *Sus cristatus*, lent by Sir Walter Elliott, K.C.S.T. 5. Skull of *Sus barbatus* wrongly named *S. verrucosus*, and needlessly *Euhys barbatus* in some mammalogical catalogues.

From these and other data the author bases the subjoined conclusions:—

1 The domesticated pig of Pre-Roman times, as exemplified at least by the specimens from the interment referred to, appear to resemble *Sus scrofa*, var. *ferus*, rather than *S cristatus*, or the domestic variety, *S indicus*

2 On the other hand, *S cristatus*, the Indian wild hog, appears to him, whilst being readily and always distinguishable from *S scrofa*, var *ferus*, to differ from it, mainly by the retention permanently of certain structural conformations which were only temporarily represented in the European wild species The third molars of the male, *S cristatus*, varied, however, concomitantly with its canines, and showed a much larger development of their posterior lobe, than either *S scrofa*, var *ferus*, or the females of their own species The rearmost lobe, however, of the posterior molar, varies a good deal in *S scrofa*, var. *ferus*, irrespective of sex

3 Bearing in mind the elasticity of the swine type and the power for changing which their domestication has shown to possess, Dr Rolleston has less difficulty in conceiving that the so-called *S indicus* was really a modified *S cristatus*, than that it had been evolved from any *Sus*, such as *S leucomystax*, from countries further away from Europe than India *S cristatus* had the malar border of the lachrymal always marked by the relative shortness insisted on by Nathusius It had not the relatively wider palate, but upon this point too much weight had been laid.

4 A skull of a wild sow, from the alluvium, later in date than the "river gravels," near Oxford, combined the short lachrymal characteristic of young pigs and of *S. cristatus*, with the worn down teeth, elongated facial skeleton, and disproportionally small size of an old wild sow, *S scrofa*, var *ferus* Such a combination of characteristics tended to suggest carefulness as to accepting the Torf Schwein *S scrofa*, var *palustris*, of Rutimeyer, as a distinct species, or taking even such a point as the shortness of the lachrymal as constituting a specific difference

5 The simplicity of the third molars in the very large skull of *S barbatus* appear to be of greater value, as the rugose condition might have been expected to be forthcoming in so large, so well armed, and so well fed a *Sus* as this from Borneo

6 The true *S verrucosus* differs from *S barbatus* in having the lachrymal's malar edges long, relatively to its orbital, as well as in the peculiarities which its specific name implies. These peculiarities were reproduced in the old Irish "Greyhound Pig" figured by Richardson "Domestic Pigs," p 49, Ed. Waine

7 The often-quoted paper by Dr Gordon, *Medical Times and Gazette*, May 2, 1857, p 429, led us to suppose that *Taenia solium* of man, infested the domestic pig of India, as it does those of other parts of the world The facility with which the pig lends itself to domestication enables us to understand how the many-sided commensalism which now exists between man and that animal may have set up in very early times. Indeed the particular results of their commensalism which their solidarity, as regards the alterations of the generations of *Taenia solium* represents, suggests that their co-existence in time must have been more extensive than even the co-existence in space ascribed to them, not quite correctly, by Gibbon ("Decline and Fall," chap. ix. note 9, p 392, Smith's edition)

PHOTOGRAPHIC PROCESSES[1]

II.

WE next pass on to other applications of the dichromates for the production of prints, and the first I shall demonstrate is that known as carbon printing, but which is perhaps more correctly termed the autotype process It is dependent on the oxidation of gelatine, one of the substances which you may have already guessed would be capable of being acted upon by the dichromates If, then, we have a film of this gelatine impregnated with potassium dichromate, and after drying it be exposed to light, it will be found that all the portions acted upon will become insoluble in hot water; that is, supposing the duration of the exposure be of sufficient duration, and if the light be sufficiently intense. Imagine now that beneath a negative of delicate gradations of light and shade we place a film of sensitive gelatine, supported for convenience sake on paper, and allow sunlight to act upon it. After a time, in what condition will the gelatine be? It will be partially insoluble, more particularly on the surface next the negative, and the lights and shades will be represented by different depths of insoluble matter, according to the intensity of light penetrating through the various parts of the negative. I must here pause, and try and explain why this is At first sight it might seem that the *whole of the thickness of the film* ought to possess different ratios of solubility This is not true, however, the solubility is affected to different depths That coloured component of white light which is principally effective in producing the chemical change is blue, and which consequently finds a difficulty in piercing through the orange-coloured dichromate The amplitude or height of the blue wave is continually diminished, till finally it is almost extinguished. Now the intenser the white light the greater will be the original amplitude of this wave, and it is at once apparent that the limit of amplitude, which is effective to cause the chemical change, will be reached at a greater depth by those rays of light which were originally the brightest. A little reflection, then, will show you that the soluble part of the gelatine will principally be next the paper, and on immersion in hot water the viscous unaltered gelatine would remain imbedded between it and the outer insoluble surface Though several ingenious methods have been tried to render the support on which the gelatine rested sufficiently porous to allow the occluded parts to be washed away, yet, so far, no attempt has been completely successful To get over the difficulty the principle has been adopted of transferring the gelatine film to a temporary support, the outside surface being caused to adhere to it Evidently, by this means, the soluble gelatine can be washed away when the paper is peeled off, and a raised image insoluble in water would remain, which eventually may be transferred to its final support The temporary supports, usually employed are metal plates, glass, paper coated with an insoluble compound, &c A picture in gelatine alone, however, would be, comparatively speaking, of little value, as it is almost colourless, but if pigments be mixed with it the objection disappears. In the autotype process the gelatine is mixed with colouring matter and a coating is given to a piece of paper When dried the gelatine can be rendered sensitive by floating its surface on a solution of potassium dichromate, and after again drying is ready for printing Such a piece of prepared paper, or carbon tissue as it is technically called, we have here It has already been exposed beneath a negative, but no trace of any image is apparent, as the dark colour of the pigment masks it entirely In order to judge of the amount of light received during exposure resort then is had to what are called actinometers. The details of the instruments I will not enter into, suffice it to say it is usual to judge the depth of printing by the colour given to silver chloride Placing then the exposed tissue, gelatine side downwards, beneath water in which a zinc plate has already been immersed, and bringing the surfaces of the two together, they are withdrawn from the water with a film of moisture between You will notice that I left the print in the dish but a very short time, for a reason which you will presently understand By passing this "squeegee" (which is a bar of wood from which a thick strip of india rubber projects) over the back of the paper I drive out all the water from between the surfaces, and you see how the gelatine film clings to the zinc And why is this? You will find that it is not naturally adhesive, the light has changed the quality of the gelatine in this respect, then why does it hold so tight to the metal plate? Simply owing to the moisture left in the paper, the soluble gelatine soaks it up and expands. It cannot well expand laterally, so it expands upwards, and a partial vacuum is created between the gelatine and the plate. Now you see why I left the print in the water such a short time Had I left it in longer the total expansion would have taken place, and the necessary vacuum could not have been created when it was pressed on to the zinc plate

Now that it is firmly held, I can place it in hot water and remove the paper. It easily peels off, and the solvent action of the fluid can have fair play As I move it up and down in the trough, you can see the gelatine running over the surface. After a few minutes it is clean, and the development is finished On this plate I have another print which has already undergone similar treatment, but has been allowed to dry. This piece of

[1] Lecture by Capt Abney, R E, F R S, at the Loan Collection, South Kensington Continued from p 241.

transfer-paper is now heated in very hot water, and applied to the surface. It is "squeegeed" on to it, and you see it adheres, this time, however, by its "stickiness." Here is another print in the same stage, but the adhering paper is dry. Raising one corner of it by my nail, I can grasp it in my fingers, and the finished print strips off the plate held in position by the paper.

Such are the usual manipulations in autotype printing, and the pictures produced by this method should be permanent, and they must be as permanent as leather, or as the pigment which is employed to give visibility to the gelatine image. As I mentioned before, there are various modifications of the process; for instance, one is to develop the picture on the permanent support destined to bear it, using this instead of the zinc plate. A little consideration will show you that in this case the negative employed must be reversed.

We now come to a large class of printing processes known as photo-mechanical. And here I should state that the term photo-mechanical is applied to such processes as are independent of light for production of prints after that agency has once furnished a plate or means of producing a plate. The first of these that I shall attempt to describe is that known as the Woodbury type after the inventor, Mr. Walter Woodbury. The following outline will give some idea of the methods resorted to:—

A skin of gelatine is prepared somewhat in a similar manner to that which I shall describe in the heliotype process, only for this it receives a tough film of collodion on one surface. This surface is placed next a negative on glass, and the light from an unclouded sun or from a luminous point (such as the electric light) is allowed to fall on it. Owing to the thickness of the gelatine employed, this method of exposure is necessary in order to secure sharpness. The print is developed as in the autotype process, and we get an image in great relief, formed by the insoluble gelatine, resting on the tough collodion film. When dried, this relief picture is placed on the surface of a flat, soft metal plate, and, by hydraulic pressure, is forced into it, furnishing a mould, perfect in all its parts. The wonder is at first excited that the gelatine does not break under the enormous weight brought to bear upon it, but when it is recollected that ferns and grasses can be made to furnish similar impressions, the astonishment is diminished, in that the substance employed is now in a leathery condition.

Apparently it matters little as to which side of the relief is pressed into the plate. In one case we should have to use a reversed negative, whilst in the other any ordinary negative may be employed. This is important to the photographer, as may be surmised.

Before us we have the negative, a relief from it, and a mould taken from the relief. This mould is now placed in this press, which consists of a flat plate (which can give slightly in any direction, and is capable of being raised or lowered) and a flat hinged top, to which is affixed a perfect plane of glass. When this lid is brought down on to the mould, the lower lid gives till perfect contact is got between the two surfaces; a species of clamp enables the lid to be kept in position. You see on placing this piece of paper in the mould, the clamp closes with difficulty, but a little mechanical contrivance attached to it causes a great pressure to be brought to bear. Opening the press once more, a little warm gelatine, which has been impregnated with colour, is poured on the mould, and a piece of resinised paper placed over it; the press is again closed. The mass of cold metal soon cools the gelatine, and on opening the lid, it is found that the excess of gelatine has been squeezed out beyond the mould, and on lifting off the paper, a picture is found adhering to it. This image is really formed in precisely the same way that a cook forms her jelly in a mould, though the colouring matter in this case is somewhat different. When dry, the picture is rendered insoluble in water by passing it through an alum bath. At first sight, this process might seem to be slow, but when it is remembered that half a dozen moulds can be made from the same relief, it requires no great exercise of the imagination to surmise that the pictures may be produced almost as rapidly as a lithograph. I referred to the relief necessary to produce the mould. From what I have described it will be seen that the dried relief must be as great as the *wet print* of the autotype process in order to produce the same gradations.

The last process I shall describe is known as the heliotype process, and I have chosen it for demonstration as I am practically acquainted with its working at Chatham, and not from any inherent superiority it may possess. It is a type of all the photo-mechanical processes, if we except Woodbury-type, and it is to such as these that we must look for our book illustrations, though I am still in hopes that we may have a really good process for surface printing from a metal block, capable of being set up with type. We have a promising example of this latter process in what is known as Dallastint, the offspring of Mr. Duncan Dallas; but as it is a secret process I cannot say anything regarding its production.

In the heliotype process there are various operations.

To begin with, there is the preparation of the gelatine film on which the image is printed.

The manner of preparing it is as follows:—Gelatine is dissolved in water by aid of heat, and to it is added a sensitiser which consists of potassium dichromate, to which a small quantity of chrome alum is added. Now here I must remark that this chrome alum forms an important part of the process. Gelatine we know ordinarily dissolves in hot water, but if it be impregnated with chrome alum not only does it render the gelatine insoluble, but it also toughens it in a marked manner when it is wetted. When the subsequent operations are explained, the importance of this property bestowed on the gelatine will be manifest. The solution of gelatine (with this sensitiser mixed in it) is flowed over a carefully levelled glass plate to such a depth that in drying it has the thickness of a piece of Bristol board. The glass plate may be ground and very slightly waxed, or it may be coated with a dilute solution of india-rubber to facilitate the gelatine leaving it, when it is required to be employed for printing purposes. A negative (which must be what is known as a reversed negative) is placed in a pressure frame, the gelatine is stripped off the plate, and the surface, which was next the glass, is in contact with the taken image. The necessary exposure may be estimated by an actinometer or by examining the image in the printing frame. When judged to be sufficiently printed, the back of the print is hardened by exposure to light. This operation gives toughness to the gelatine and renders it capable of resisting the treatment it has subsequently to undergo.

The skin of gelatine is next taken, and immersed for a few seconds in cool water (in practice a temperature of over 60° F. is found to be the best). A pewter or other metal plate, coated with india-rubber is now placed underneath it, and the film caused to adhere to it by the use of the squeegee. The pressure of the atmosphere causes the adhesion as it does in the autotype process. For convenience sake the edges are now run round with a solution of india-rubber in benzole and paper pasted round them, to prevent the water getting beneath the skin. The plate is then immersed in cold water for about half-an-hour, to soak out the unaltered dichromate, and it is ready for use as a printing surface after the superfluous water is blotted off.

The gelatine skin is all in an insoluble state owing to the presence of the chrome alum; but further, the part where the light has acted fully will not absorb water, whilst that which only partially absorbs water has only been partially acted on by light, and the part wholly unacted upon absorbs it greedily. When a roller containing greasy ink is passed over it, those parts which contain a great deal of water take no ink, particularly if it be stiff ink. The parts containing a little water take the ink lightly, whilst those parts which have refused to imbibe any moisture take it greedily. Evidently here we have a means of obtaining a picture of half-tone subjects in printers' ink. Another point is that thin ink takes better in a partially exposed portion than does a thick ink, hence to bring out the half-tone it is customary to use two or even three inks of different consistency. The printing plate is generally placed in the bed of an ordinary printing press and rolled up with a soft roller or rollers, charged with the printing inks. The impressions are pulled off as for letter press, though more force is necessary. In order to have clean margins a mask is cut of the proper dimensions, and brought to certain register marks. The paper, usually employed for receiving the impressions, is enamelled, the enamel being formed of barium sulphate and gelatine. Any ordinary paper, however, may be used, if it have the power of taking up the ink. On the walls of the exhibition are some photographs printed on ordinary drawing paper, and they are effective in their way.

Mr. Edwards, the patentee of this process, proposed to use a series of gelatine printing surfaces from the same negative, to form a species of photo-chromotype, and I have seen some specimens which are very successful. Little seems to have been done, however, in this direction at present. When drawing your attention to the manufacture of the gelatine skins there was one point to which I did not allude. You may make your skin of jelly or of blanc mange. I have found that a certain proportion of milk added to the gelatine in lieu of the water gives more delicate pictures than does gelatine

alone. There are several kindred processes worked at present, amongst which I must notice that of the Autotype Company. In their process an exceedingly thin layer of gelatine is formed on the plate and hardened by means of gum resins. The gelatine is not removed from the plate, but it is printed from whilst still on it. The film is hardened from the back. The glass plate can be inked in as described for the heliotype process, and can be pulled in a lithographic press or in an ordinary printing-press. M. Thiel, of whose process we have beautiful examples on the walls of this room, uses an ordinary lithographic printing-press.

I have only been enabled to give you a brief outline of these few processes, specimens of all of which are to be found in this exhibition. Short as have been the descriptions, I hope, however, that they have been sufficient to enable you to see the immense strides in the methods of producing prints that have been made in the last dozen years. When we consider that the autotype, the Woodbury type, and all the other mechanical printing processes have been worked out in that time, you will see that the inventive faculties of those who labour in the art-science have not been allowed to lie dormant. Perhaps in no other occupation is there such a field for discovery and improvement as in photography; and considering the many workers in it, and the large industry it represents, we may surely hope that in 1886 we may again be able to record a still further advance; it may be, perhaps, in the line I have already indicated, and in colour pictures.

OUR ASTRONOMICAL COLUMN

THE COMET OF 1686.—This comet, so far as the European observations are concerned, offers a very similar case to that of the comet of 1533, for which two totally different orbits have long appeared in our catalogues. As regards the latter, it was shown by Olbers that the observations of Apian between July 18 and 25 were insufficient to decide whether the true direction of motion was in the order of signs or the opposite, the node at the commencement of Leo or the end of Capricornus, or the perihelion in Cancer or in Scorpio; but the publication of the Chinese observations since Olbers wrote, has afforded evidence which tends to give the preference to his direct orbit, as already intimated in this column. The best observations of the comet of 1686, are those of Père Richaud at Pau, on four mornings between September 7 and 15; from his positions for the 7th, 10th, and 15th, the following orbit was obtained, and for the sake of comparison Halley's orbit, the only one previously computed, is copied.

	New Orbit.	Halley's Orbit
Perihelion Passage, G.M.T. ..	Sept. 19·2040 ...	Sept. 16·6063
Long. of Perihelion	23° 35′·4 .	77° 0′·5
,, Ascending Node ...	149 13·2 ...	350 34·7
Inclination	32 10 1 ...	31 21·7
Log. Perihelion Distance	9 48730 ...	9·51188
Motion.	Retrograde.	Direct.

If we compare these two sets of elements with Richaud's places, we find the differences between calculation and observation to be, for 16h. Paris M.T., as assumed time—

	New Orbit. Long.	New Orbit. Lat.	Halley's Orbit. Long.	Halley's Orbit. Lat.
	° ′	° ′	° ′	° ′
Sept. 6 ...	0 0 ...	0 0	+0 11 ...	−0 32
,, 8 ...	−1 18 ...	+0 11	−0 27 ..	0 0
,, 9 ...	−0 26 .	+0 14	+1 32 ...	−1 3
,, 14 ...	0 0 ..	0 0	−0 8 ...	−0 4

So that from these eight days' observations only it would be difficult to give a decided preference to either orbit. But it fortunately happened that before the comet was seen in Europe, it had been a very conspicuous object in more southern latitudes; at Para, in Brazil, it had been observed during the whole month of August, the nucleus as bright as stars of the first magnitude, with a tail 18° in length; in Siam by the French Jesuit missionaries, who its position approximately between August 17 and 23, and at Amboyna on August 15, a little south of the belt of Orion.

On comparing the two orbits with the Siam observations, it is at once evident that they decide in favour of Halley's elements, and on making a further calculation in which the August positions, which are only rough ones, are introduced, the following orbit finally results:—

Perihelion Passage, 1686, September 15·8249 G.M.T.

Longitude of Perihelion	75° 58′·4	Equinox of 1686.
Ascending Node ...	354 3·8	Equinox of 1686.
Inclination	34 55·7	
Log. Perihelion Distance	9·52636	
Motion ...	Direct.	

On the morning of August 17 the comet was distant from the earth 0·316, and at the time of Richaud's last observation, 0·973.

While writing on a cometary subject, we are reminded of what appears to be an unusual dearth of comets not of known period, in these parts of the system since the last one was detected by M. Borrelly on December 6, 1874, or more than eighteen months ago. It is true that generally the weather during this interval has been abnormally bad for such work as comet-hunting; still considering that several of the observers who of late years have given most attention to the search for these bodies, are located in very favoured climates, this appears hardly to explain the absence of any discovery. It may be anticipated that a systematic search for comets in the southern heavens will soon be organised by some zealous amateur in the other hemisphere; it is certain that he would in this way be likely to render material assistance in the advancement of cometary astronomy, and as we have before urged, he might succeed in bringing to light again one or two comets which were assuredly moving in elliptical orbits of short periods when last observed, but from one cause or another have since got adrift, and are not so likely to be recovered in the northern as in the southern hemisphere.

NEW MINOR PLANET.—M. Leverrier's *Bulletin International* of July 13 notifies the discovery by M. Paul Henry, at the Observatory of Paris, on the previous evening, of another small planet in R.A. 15h. 56m., N.P.D. 111° 59′. This planet, which is estimated 12·5m., is called No. 164, but it is to be remembered that we do not know the actual positions of so many as 164 of these bodies, and until the elements of any newly-detected one are well determined, there is the chance of identity with one or other of several which have been previously observed and even calculated, but for want of continuous observation are now lost.

A PHYSICAL SCIENCE MUSEUM

THE President of the Royal Society, Dr. Hooker; Mr. Spottiswoode; Dr. Burdon Sanderson; and Dr. Siemens, had an interview on the 17th inst. with the Lord President of the Council, the Duke of Richmond and Gordon, and presented the subjoined memorial from gentlemen who have been connected with the Loan Collection of Scientific Apparatus at South Kensington. His Grace discussed the subject of the proposed permanent Science Museum with the deputation, and stated that he would consult his colleagues.

MY LORD DUKE,

We, the undersigned, beg to submit for your Grace's consideration the importance of establishing a Museum of Pure and Applied Science; that is to say, a Museum to contain Scientific Apparatus, Appliances, and Chemical Products, illustrating both the history and the latest developments of Science; where the methods and results of investigations which have marked important stages in the advancement of Science may be studied, and where also the most highly perfected instruments of the day may be found.

Among the various advantages which in our opinion would accrue from the establishment of such an Institution,

we would mention the following. Investigators would be saved much time and labour by being enabled to see how far, and by what processes, others have advanced in the line of research which they may be pursuing: thus leading them to a knowledge of the facts and laws already established. From an educational point of view such a collection would assist teachers, by enabling them to select, or by showing them how to construct, the best apparatus for illustrating the subjects of their lessons. Great benefit would also accrue to the constructors of Mechanical and Philosophical Apparatus from being able to refer to the original Apparatus which they might be required to reproduce or to improve. To every one connected with Experimental Science, it would be of great service to see the actual instruments, many of which could otherwise be only known to them by description, and, under proper supervision and instruction to learn their actual manipulation and performance. We would also contemplate lending to investigators, under suitable restrictions, such instruments as might be profitably employed in the researches they were pursuing.

In considering this subject our attention has naturally been directed to the existing Museum of Patents. While fully recognising the value of many of the objects now belonging to that collection, we are of opinion that, as standing alone and purely as subjects of a patent, their value is far less than if they formed part of a general collection, and were placed in juxtaposition with instruments of a similar nature, some of which, though not patented, are better adapted to their purpose, and of greater instructional value. The object of a Scientific Museum is the promotion of knowledge, and the establishment of the scientific principles which must underlie all invention; and it would not only prove of great advantage to both scientific investigators and the public if the two objects could be combined in one undertaking, but we believe that the objects of a Patent Museum would be better served by a museum of the character here proposed than by a special collection, such as has hitherto subsisted. We are decidedly of opinion that the state of knowledge in reference to any invention would be only very imperfectly represented by the exhibition of patented instr uments and products only.

In support of the views which we have ventured to submit, we would draw your Grace's attention to the Fourth Report of the Royal Commission on Scientific Instruction, §§ 80-94. In § 93 the Commission state:-"We accordingly recommend the formation of a Collection of Physical and Mechanical Instruments; and we submit for consideration whether it may not be expedient that this Collection, the Collection of the Patent Museum, and of the Scientific and Educational Department of the South Kensington Museum should be united and placed under the authority of a Minister of State."

We understand that the Royal Commission for the Exhibition of 1851 has offered to erect a building for the purpose contemplated in this memorial, and we would desire to point out that the purchase of objects need not entail any large outlay of public money. We contemplate the gradual formation of a collection of such objects as might be voluntarily left at the close of the existing Loan Collection, and others which might be contributed from the existing Patent Museum and other public departments, from the parliamentary grants administered at the request of Government by the Royal Society, and from such private societies and individuals as might be disposed to avail themselves of the Museum as a depository of scientific apparatus, appliances, and chemical products.

We have the honour to be, my Lord Duke,
Your Grace's obedient Servants,

(Signed) J. D. Hooker, President of the Royal Society.
John Evans, F.R.S., Chairman of the Conferences in the Geographical Section.
E. Frankland, F.R.S., Chairman of the Conferences in the Chemical Section.
J. Burdon Sanderson, F.R.S., Chairman of the Conferences in the Biological Section.
C. W. Siemens, F.R.S., Chairman of the Conferences in the Mechanical Section.
W. Spottiswoode, Treasurer and Vice-President R.S., Chairman of the Conferences in the Physical Section.
Charles Brooke, F.R.S.
Alfred S. Churchill, Chairman of the Society of Arts.
William Kitchen Parker, F.R.S.
H. W. Bristow, F.R.S., Director of the Geological Survey of England.
William B. Carpenter, F.R.S.
Latimer Clark, late President Soc. Tel. Engineers.
W. H. Flower, F.R.S., Conservator Hunterian Museum.
J. H. Gilbert, F.R.S.
Robert Main, F.R.S., Radcliffe Observer.
Fredk. Jno. Evans, V.P.R.S., Capt. R.N., Hydrographer of the Navy.
P. de M. Grey Egerton, F.R.S.
Hampton, F.R.S., President of the Institute of Naval Architects.
Joseph Prestwich, F.R.S.
T. M. Goodeve, M.A.
W. de W. Abney, Capt. R.E., F.R.S.
G. W. Royston Pigott, M.A., M.D., F.R.S.
Robert H. Scott, F.R.S., Director Meteorological Office.
George Robert Stephenson, F.R.S., President Institute Civil Engineers.
F. H. Wenham.
George Bentham, F.R.S.
Nevil S. Maskelyne, F.R.S.
H. S. Eaton, President of the Meteorological Society.
E. Atkinson, Treasurer of the Physical Society.
F. A. Abel, F.R.S., President of the Chemical Society.
T. Hawksley, President of the Institute of Mechanical Engineers, past President of the Institute of Civil Engineers.
William H. Stone, F.R.C.P., &c.
W. J. Russell, F.R.S.
David Forbes, F.R.S.
Richd. Collinson, Vice-Admiral, Deputy Master of the Trinity House.
B. Woodcroft, F.R.S., late Superintendent of Patent Office Museum.
C. W. Merrifield, F.R.S.
Andw. C. Ramsay, F.R.S., Director General Geological Survey.
C. P. B. Shelley.
James Baillie Hamilton.
F. Eardley-Wilmot, F.R.S., Major-General.
Henry Cole.
Warren De La Rue, F.R.S.
Frederick Guthrie, F.R.S., Prof. Physics, Royal School of Mines.
C. O. F. Cator.
Thomas Savage.
Alfred Barry, D.D., Principal of King's College
Wm. Chappell, F.S.A.
A. J. Mundella, M.P.
William C. Unwin, Prof. Engineering, Indian C. E. College.
George T. Clark.
Joseph Woolley, LL.D.
John F. Twisden.
Richard Strachey, Major General, F.R.S.
Frank Bolton.
D. Glasgow.
William Rutherford, M.D., F.R.S.
Henry E. Roscoe, F.R.S.
J. Hopkinson.
A. W. Reinold.
John Tyndall, F.R.S.
John Torr, M.P.
Aberdare, President of the Royal Horticultural Society.
Robert James Mann, M.D.
Albert Gunther, V.P.R.S.

H. C. Rawlinson, F.R.S., late President Royal Geographical Society.
W. B. Baskcomb.
James K. Shuttleworth.
Geo. Busk, F.R.S.
Geo. J. Allman, F.R.S., President of the Linnean Society.
J. Arthur Phillips.
T. H. Huxley, Sec. R.S.
E. Ray Lankester, F.R.S.
H. C. Sorby, F.R.S., President of the Royal Microscopical Society.
W. T. Thiselton Dyer, Assistant-Director, Royal Gardens, Kew.
Henry W. Acland, F.R.S., President of Medical Council.
H. W. Chisholm, Warden of the Standards.
D. T. Ansted, M.A., Cant., F.R.S.
J. H. Gladstone, F.R.S., Fullerian Professor, Royal Institution.
J. Scott Russell, F.R.S.
A. Lane Fox, Colonel, F.R.S.
Rayleigh, F.R.S.
Robert S. Ball, LL.D., F.R.S., Astronomer Royal, Ireland.
H. C. Seddon, Major, R.E.
Charles V. Walker, F.R.S., President of the Society of Telegraphic Engineers.
Joseph Whitworth, F.R.S.
G. Carey Foster, F.R.S., President of the Physical Society.
Balfour Stewart, F.R.S.
R. B. Clifton, F.R.S., Professor of Experimental Philosophy, Oxford.
W. F. Barrett, Prof. Physics, Royal College of Science, Dublin.
J. Norman Lockyer, F.R.S.
Francis Galton, F.R.S.
J. Cameron, F.R.S., Major-General, Director Ordnance Survey.
M. Foster, F.R.S.
E. A. Schafer.
B. Samuelson, M.P.
E. Klein, F.R.S.
W. N. Hartley.
Francis Guthrie, LL.B.
P. Martin Duncan, F.R.S., President of the Geological Society.
P. L. Sclater, F.R.S.
J. E. Davis, Capt. R.N., Hydrographic Department, Admiralty.
H. Dent Gardner.
John Allan Brown, F.R.S.
William Hackney.
Ettrick W. Creak, Staff Commander, R.N.
W. H. Preece.
W. Chandler Roberts, F.R.S.
A. B. Kempe, B.A., Barrister-at-Law, Western Circuit.
Alex. Crum Brown, Professor of Chemistry, Edinburgh University.
James Dewar, Professor of Mechanism, Cambridge.
Urban Pritchard, M.D.
R. H. M. Bosanquet, M.A., F.R.A.S., F.C.S., Fellow of St. John's College, Oxford.
Sydney H. Vines.
Alfred E. Fletcher.
Herbert M'Leod, Prof. of Experimental Science, Indian C.E. College.
Alex. B. W. Kennedy, C.E., Prof. Engineering, University College.
Arch. Geikie, F.R.S., Director, Geological Survey, Scotland.
Cornelius B. Fox, M.D., F.M.S.
Nicholas Brady, M.A.
Thomas Stevenson, F.R.S.E., F.G.S., M. Inst. C.E.
John Jellett, D.D., F.R.S.
Thomas Pigot, Prof. Engineering, Royal College of Science, Dublin.
J. P. O'Reilly, Prof. Mineralogy and Mining, Royal College of Science, Dublin.
T. Lauder Brunton, M.D., F.R.S.
J. E. H. Gordon.
W. Galloway, Prof. Chemistry, Royal College of Science, Dublin.
Henry E. Armstrong, F.R.S.
Thomas Andrews, LL.D., F.R.S., President of the British Association.
James Thomson Bottomley, M.A., F.R.S.E.
W. F. Donkin.
Claude R. Conder, Lieut. R.E.
Charles E. De Rance, F.G.S., H.M. Geological Survey.
Nathl. Barnaby, Chief Constructor of the Navy.
W. Topley.
J. Clerk Maxwell, F.R.S., Prof. of Experimental Physics in University of Cambridge.
G. G. Stokes, Sec. R.S. Lucasian Professor, Cambridge.

NOTES

THE current number of the *Fortnightly Review* contains an article by Dr. Bridges, in which he tries to prove that Harvey did not discover the circulation of the blood by vivisection. Harvey's own statements are so explicit, and the methods he employed have been so often expounded, that there is little new to be said on the point. Harvey, as Dr. Bridges admits, discovered the true functions of the heart, and inferred the existence of the complete systemic circulation by observations on living animals, interpreting the facts observed by aid of the faculty of reasoning. Malpighi demonstrated the capillary part of the circulation by other observations on living animals, dealing with his new facts by aid of the same faculty. But to say that the movements of the heart were discovered by vivisection and the brains of Harvey, but the circulation of the blood "by the microscope of Malpighi" is as absurd as to ascribe the glory of the former discovery to Harvey's scalpel and that of the other to Malpighi's brains.

THE following are the numbers of visitors to the Loan Collection of Scientific Apparatus during the week ending July 15:—Monday, 3,464; Tuesday, 3,300; Wednesday, 602; Thursday, 495; Friday, 451; Saturday, 3,403; total, 11,715. During the present week 13 demonstrations of apparatus were given on Monday, 11 on Tuesday, 5 on Wednesday; 6 are to be given to-day, 5 on Friday, and 5 on Saturday.

THE annual meeting of the Helvetic Society of Natural Sciences will take place at Basle, on August 20-23. Scientific men of all countries are cordially invited to the meeting; and those who wish to make any communication are requested to write, before August 1, to Dr. H. Christ, 5, Baumleingasse, Basle.

THE Scientific Societies of Belgium held their first united Congress at Brussels this week, from the 16th to the 18th. The following, we learn from the *Society of Arts Journal*, are some of the subjects which have been discussed:—Greater facilities for the transmission of scientific objects; as to the opening of public scientific institutions at convenient hours, and especially in the evening; the organisation of libraries and scientific collections in the towns and communes; the publication of elementary treatises on various branches of science; establishment at one of the littoral towns of a collection of works concerning the coast; a study of the geological formation of the district round Brussels; the part played by molluscs in nature; the malacological zones of Belgium. On the 18th there was to be a scientific excursion into the environs of Brussels.

AT a meeting of the Council of the Yorkshire College of Science, held last Friday, an offer by Mr. George Salt, of 150*l.* a year for three years as a temporary provision for a professorship of Biology, was accepted, Mr. Salt's stipulation that Mr.

L. C. Miall, F.G.S., be appointed professor being also agreed to. Mr. Miall will also deliver a short course of lectures annually at Bradford.

We rejoice to hear that *L'Explorateur* was mistaken in announcing the death of Dr. Petermann. The French journal seems to have been led astray by the death of Prof. A. H. Petermann, the distinguished orientalist.

On Saturday, July 8, the French and Swiss Alpine Clubs met together at Giromagny, to ascend a number of mountains in the French Vosges; a number of interesting observations were made.

The Awards made by the Council of the Institution of Civil Engineers for original communications during the Session 1875-76, have just been announced. Fifteen out of twenty-three communications have been rewarded, including a Telford medal and premium for "Motion of Light Carriers in Pneumatic Tubes," by Prof. W. C. Unwin, B.Sc. Telford premiums have been bestowed for "Movement of Air in Pneumatic Tubes," by C. Bontemps; "Pneumatic Transmission of Telegrams," by R. S. Culley and R. Sabine; "Floods in England and Wales in 1875," by G. J. Symons; "Evaporation and Percolation," by C. Greaves; "Tidal Changes in the Mersey," by J. N. Shoolbred, B.A. The Miller Scholarship of the value of 40*l.* a year for three years was gained by the Hon. R. C. Parsons, B.A., for an inquiry into the "History and Theoretical Laws of Centrifugal Pumps."

Mr. W. Vivian, of Mwyndy, Llantrisant, Glamorganshire, sends us the following instance of a joint-stock concern in the poultry yard. Two hens sat on, or by, one nest, and thus between them hatched one chick. They have since, for some weeks been parading the yard, each clucking and manifesting all the anxiety and care of a true mother over this one. The hens never quarrel, or show the least appearance of jealousy or rivalry.

A meeting of the West Riding Geological and Polytechnic Society was held at Settle on Wednesday week. The meeting was well attended, and Mr. Tiddeman gave an excellent address on the history, method of working, and the results that have been brought to light by the exploration of the Victoria Cave, Settle.

Further particulars have been published concerning Gessi's circumnavigation of Lake Albert Nyanza. He found it 140 miles broad by 50 wide. No river of importance enters it, the south end is shallow, and the lake seems subject to violent storms. The true Nile, after leaving the lake south of Duflé about 100 miles, splits into two branches, one of which goes to Duflé and Gondokero, the other, the natives say, goes far inland. Colonel Gordon had no news of Stanley on May 2, but expects he went across from Victoria Lake, saw the south end of Albert Lake, and has got into a nest of lakes, which, Colonel Gordon thinks, exist between the Albert and the Tanganyika.

We have received the Proceedings of the American Oriental Society for May and November, 1875, and May, 1876. At these meetings many valuable papers on the department with which the society is connected, were read; among these is one by Prof. W. D. Whitney replying to some criticisms of his work by Prof. Max Muller.

The Paris Society of Agriculture and Insectology has asked from the Municipal Council of Paris, whose zeal for instruction is laudable, the grant of a piece of ground at Montsouris for the purpose of establishing a model apiary, a botanical collection of all plants likely to be of use in feeding bees, a model establishment of sericiculture, and a collection of all trees likely to be of use in feeding silkworms. The request is to be granted on condition that the establishment be open free to the pupils c the several municipal schools.

Satisfactory accounts are given of the boring of the shai for the Channel Tunnel. A depth of 80 yards has bee reached, and no fault has been observed from which any diffi culty may be expected in the execution of the Tunnel.

Violent shocks of earthquake were felt again on the 5tl inst. at Corinth and the surrounding district. The direction c the motion was east to west. Shortly after noon on Monday a earthquake occurred in Vienna. Three violent shocks, lastin two seconds, were felt. A panic ensued. Several houses ar damaged, and a portion of the old walls has been split.

We have received the Forty-second Annual Report of th York School Natural History, Literary, and Polytechnic Societ This must surely be the oldest School Society in the kingdon The Report, of only four pages, shows that a considerab amount of work has been done in the various departments wi which the Society deals, and we should think that the Socie is an important element in the educational means of the schoo

The Twelfth Annual Report of the Lewes and East Suss Natural History Society states that the Society is numerical and financially in good condition. The Society is doing a fa amount of good field-work, and contemplates the publication lists of the fauna and flora of East Sussex.

The *Geographical Magazine* for July contains a paper, wi maps, by Mr. Ravenstein, exhibiting some interesting conclusio as to the birthplace and migrations of the populations of t British Isles, drawn from the census tables. The magazine al contains some important statistics on Danish Greenland, furnish by Dr. Rink, a paper on the Andaman Islands, an account Schweinfurth and Güssfeldt's recent journey into the Arabi Desert of Egypt, and a vindication of genuineness of Verrazan narrative, by Mr. R. H. Major.

The Municipal Council of Paris has voted, in accordance w the suggestion of M. Leverrier, a sum of 30,000 francs for t purpose of constructing precision clocks at the Exchange, Tribu de Commerce, and Hôtel de Ville. A competition will opened between the clock-makers. All these clocks are to connected together electrically, and will distribute the time the several parts of the city. The perplexing discrepa between the different public clocks in Paris will be abolis entirely.

A meeting was held on Tuesday in connection with the p posal to establish a Museum of Hygiene at University Colle London, as a memorial to the late Dr. E. A. Parkes, F.R Subscriptions to the amount of 675*l.* were announced.

Mr. Prescott G. Hewitt, F.R.S., has been elected Pr dent of the Royal College of Surgeons for the ensuing year room of the retiring President, Sir James Paget.

At a recent meeting of the Paris Academy, M. Woillez scribed an apparatus which he calls a *spirophore*. It is for resuscitation of asphyxiated persons, especially those who h been in danger of drowning, and newly-born infants. It c sists of a sheet-iron cylinder, closed at one end. The bod the individual is introduced up to the neck, the aperture ro which is then closed by a diaphragm. A strong bellows, c taining more than 20 litres of air, situated without the case, c municates with this by a wide tube, and is worked by a le the descent of which causes the air to be drawn off from case, while the return motion restores the air. Through a p of glass in the cylinder, the chest and abdomen of the pa can be seen, and a rod, movable in a vertical tube, rests or sternum. When a vacuum is made about the body by depre

the lever, the external air penetrates into the chest, the walls of which rise as in life. They return to their former position when the lever is raised, and these respiratory movements may be repeated fifteen to eighteen times a minute, as in a living man. By means of a tube communicating with a reservoir, and inserted in the windpipe, M. Woillez found that a litre of air, on an average, entered the air passages at each artificial inspiration, whereas the physiological average is only a demi-litre. Thus, more than a hundred litres of air can be passed through the lungs of an asphyxiated person in ten minutes. There is no danger of rupturing the lungs, however strongly the lever be wrought, for the force of penetration of the air is never superior to the weight of the atmosphere.

THE direction of plant-growth, it is known, is determined both by light and by gravity. The geotropism, or action of gravity exclusive of light has before been examined; and recently M. Müller (Thurgau), we learn from *Flora*, has endeavoured to study the converse fact of heliotropism, by excluding the influence of gravity as far as possible. He grew his plants in a cylinder rotating about its horizontal axis. The apparatus was so arranged that the light, coming through an aperture in the shutter of a dark room, fell parallel to the axis; the bendings observed were thus purely heliotropical. Among other results he found that only those zones which were not fully grown out, showed heliotropic bendings; that the most strongly growing parts of the stem were most sensitive to one-sided illumination; that the bending takes some (variable) time to manifest itself and continues some time after removal of the cause; that the rate of bending is at first slow, gradually increases to a maximum, and thereafter diminishes; that the bending is greater the intenser the light, &c.

IN the *Upsala Universitets Arsskrift* for 1874, Dr. Hamberg gives a most interesting paper, illustrated with eight coloured maps, on the night-frosts which have occurred in Sweden during 1871-72-73, from May 20 to September 30, or during that portion of the year of most interest to agriculturists. The observations of 285 Swedish observers are elaborately discussed, from which it appears that 80 per cent. of these frosts occur with northerly winds on the day preceding and on the days following them, but that during the night of the frost either the wind is very light or the air is calm. The map exhibiting the distribution of the spring frosts shows an abnormal excess on the south or lee side of the great lakes, arising, in all likelihood, from the low temperature of these lakes in spring. In autumn, on the other hand, when the temperature of the lakes is high, no such excess of frosts occur over the region south of them. One of the most striking results is the relatively small number of frosts over the district immediately to the north of Lake Wener, a result which may be due to the remarkable deflection of the wind in summer over this part of Scandinavia, so that winds are there south-westerly when they are north-westerly and westerly on the west of Norway. Six of the maps show well the intimate relation existing between the frosts and areas of high barometric pressure, and suggest that, if desired, the telegraph might be employed to give warning of these frosts, which are so destructive to vegetation.

THE *Supplemento alla Meteorologia Italiana* for 1875, fasc. iii., is entirely occupied with an exhaustive discussion of the temperature of Modena, by Prof. Ragona, director of the Royal Observatory there, based on the observations of the twelve years ending 1874. Among the more interesting points discussed with considerable fulness, are the anomalies of temperature which have occurred during the twelve years, particular attention being given to those anomalies which show a tendency to recur about the same dates from year to year. The prevailing winds at Modena are west and south-west from November to February and north-east during the other months, and the changes of these winds is a point of the greatest importance in their relations to the anomalies of temperature which accompany them. Fasc. iv. contains an account by P. A. Serpieri, director of the Observatory of Urbino, of the earthquake which occurred in the night of March 17-18, 1875; and a notice, by Almerico da Schio, of the stations established, or in the course of being established, in the province of Vicenza, for meteorological observations, or for observations of rainfall, of weather, or of the depth of the rivers. Upwards of sixty such stations are indicated on the map of the province accompanying the paper.

TWO important publications, constituting Nos. 5 and 6 of the *Bulletin* of the U.S. National Museum, by Mr. G. Brown Goode, Assistant Curator of that establishment, have lately been published by the Interior Department. The first, a catalogue of the fishes of the Bermudas in the collection of the museum, gives the first complete account of the ichthyology of that portion of the world. These were principally obtained by Mr. Goode during a visit to the islands in the months of February and March, and are notes on the character of the species, containing many important facts in regard to their natural history. Seventy-five species in all were actually obtained, and the existence of others determined, but not established by specimens. A chief value of the paper is in the description of the colours of the fish while living, and the notes on their size and hints on their popular names, their capture, and economical value. The second publication was prepared by Mr. Goode as a classification of the collections made by the Smithsonian Institution and the United States Fish Commission for the Centennial Exhibition at Philadelphia.

THE additions to the Zoological Society's Gardens during the past week include two Royal Pythons (*Python regius*) from West Africa, presented by Mr. J. J. Kendall; a Greater Sulphur Crested Cockatoo (*Cacatua galerita*) from Australia, presented by Mrs. Baliol Scott; two Striped Hyænas (*Hyæna striata*), an Alligator (*Alligator mississippiensis*) from North America; two American White Cranes (*Grus americana*) from North America; a Green-winged Trumpeter (*Psophia viridis*) from Brazil, purchased; three Shoveler Ducks (*Spatula clypeata*) hatched in the Gardens.

SCIENTIFIC SERIALS

Journal of the Chemical Society, April.—A paper on oxynarcotine, a new opium educt, and its relationships to narcotine and narceine, is contributed by Dr. Wright and Mr. G. H. Beckett. This new body is obtained from an indistinctly crystalline mass, which, during the preparation and purification of narceine from opium liquors, is often left undissolved on boiling the partially purified narceine with water. This crude product contains the new opium alkaloid, bearing to narcotine the relationship of benzoic acid to benzoic aldehyde.—Dr. H. E. Armstrong and Mr. George Harrow contribute two papers: one on the action of potassic sulphite on the haloid derivatives of phenol, the other on the action of nitric acid on tribromophenol. The length of the chemical names made use of in these papers is positively alarming, *e.g.*, dichlorophenolorthosulphonate and diorthobromoparanitrophenol.—Mr. Cornelius O'Sullivan contributes a paper on maltose, which is intended to show that maltose, obtained by the action of malt-extract on starch, is a simple body, isomeric with cane-sugar, and not a mixture of dextrin with dextrose, as M. Bondonneau, in a note recently presented to the Academy, regards it.—Mr. M. M. Pattison Muir, F.R.S.E., gives a method of estimating bismuth volumetrically. Potassium chromate or potassium dichromate solution is run into a nearly neutral solution of bismuth nitrate until the whole of the metal is precipitated in the form of chromate. The final point of the reaction is determined by the formation of red silver chromate, when a drop of

silver nitrate is brought into contact with a drop of the supernatant yellow liquid.—Mr. Thomas Fletcher gives a brief note on a simple form of gas regulator, differing only in form from one described by Mr. Page in the January number of the *Chem. Journ.* for 1876.—Mr. Thomas Carnelley, B.Sc., F.C.S., contributes a paper on high melting-points, with special reference to those of metallic salts. The author describes a new method which he proposes for determination of high melting-points, and the results of his investigations by this new method. The principle of this new method is as follows:—In a platinum crucible a small quantity of a salt is placed, and the crucible suspended in the flame of a Bunsen's burner or of a blowpipe. If the temperature at which the salt fuses is not above a certain point, the temperature of the crucible after a time reaches that point. If, at the instant the salt is seen to melt, the crucible be dropped into a known weight of water of known temperature, and the rise in temperature noted, from the equation for specific heats, we obtain the initial temperature of the crucible at the time the salt melted, and hence the temperature at which the fusion occurred, assuming that the mean temperature of the crucible is the same as that of the salt at the moment of melting.—Numerous abstracts of papers published in other journals, together with a full account of the anniversary meeting of the Chemical Society, complete the contents of this number.

American Journal of Science and Arts, June.—We have here some interesting observations on Saturn, made by Mr. Trouvelot during the last four years with the refractors at Harvard, Washington, and Cambridge Observatories. He notes, *inter alia*, some singular dark angular forms on the inner margin of the first ring, outside the principal division of the rings; it seems due to a jagged conformation. The three outer rings have shown a mottled or cloudy appearance on the ansæ; the cloud-forms at some parts attain different heights, and change their relative positions. The dusky ring is not transparent throughout, as has been supposed; and it grows more dense as it recedes from the planet, so that, at about the middle, the limb of the planet ceases entirely to be seen through it; further, the matter of this ring is agglomerated here and there into small masses.—The "1474" line, which is reversed in the spectrum of the solar corona, coincides with one of the short lines in the spectrum of iron. It appears in ordinary spectroscopes like a fine hard black line; but in lately examining this part of the spectrum with a diffraction spectroscope armed with a silver glass "gitter platte" of 8640 lines to the inch, Prof. Young found the line to be unmistakeably double. The more refrangible line he regards as the real corona line; the other belonging to the spectrum of iron. —Mr. J. Lawrence Smith, in a paper on carbon compounds in meteorites (here concluded) arrives at some important results. The phenomena of the graphite nodules are very puzzling; the presence of such substances as free sulphur, and a hydrocarbon in the interior of the graphitic concretions was certainly not to be expected. We now know of celestial carbon (Mr. Smith says) in three conditions, viz., in the gaseous form as detected by the spectroscope in the attenuated matter of comets; in meteorites in the *solid* form, impalpable and diffused through pulverulent masses of mineral matter; also in the *solid form, but compact and hard*, like terrestrial graphite, and imbedded in metallic matter, that comes from regions in space.—From experiments on the diminution of the minute distance between two surfaces in contact, with the increase of the contact pressure (the substances being iron, brass, and plate glass), Prof. Norton found that the diminutions were very nearly the same, whatever the nature or condition of the surfaces in contact; that they were nearly independent of the extent of the surface in contact; and that the diminution of contact-distance for an increase of one ounce in the pressure, was nearly inversely proportional to the pressure.—Mr. Carey Lea describes experiments on the sensitiveness of silver bromide to the green rays as modified by the presence of other substances. Finding no red substance capable as such of increasing this sensitiveness, and on the other hand, many colourless substances which have that effect, he is confirmed in the opinion that there is no relation between the colour of a substance and that of the rays to which it increases the sensitiveness of silver bromide.—We further note a translation of M. Hartt's first report on the geological survey of Brazil, a paper by Mr. King on palæozoic divisions on the fortieth parallel, and an account of a nebula photometer, by Mr. Pickering.—Prof. Marsh describes some new fossil birds.

Archives des Sciences Physiques et Naturelles, Feb. 15.—From researches on the specific heats of saline solutions, described in this number, M. Marignac concludes that the specific heat depends not solely on the nature of the acids and bases of the salts; so that one cannot calculate it from their composition. It may be modified by other causes special to each salt, and the nature of which is still unknown. These causes do not seem to be connected with the greater or less tendency of salts to combine with water and form definite crystallisable hydrates.—It is a disputed point among physiologists whether fat is a product of decomposition of albumen. M. Secretan here describes an investigation on the subject. His experiments were on albumen decomposed in current water, and in the ground. He considers that the transformation in question is improbable, and accepts Orfila's theory, that the fat of dead bodies is only formed where there is already fat present, and an azotised matter.—In a paper on the constituents of woman's milk and cow's milk, M. Lachenal finds that the latter is richer in nitrogen, and consequently in albumenoid substances than the former, in the proportion of 3·51 to 2·53. After coagulation, the serum of cow's milk no longer contains either caseine or albumen, whereas the serum of woman's milk holds in solution a quantity of albumenoid matters which may be estimated at a half of the nitrogenised substances of the milk.—M. Gillieron studies the traces of ancient glaciers of the valley of the Wiese in the Black Forest.—In a reply to M. Soret, on the temperature of the sun, M. Violle describes some interesting observations on the radiation from incandescent steel.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, May 18.—"Note on a Simultaneous Disturbance of the Barometer and of the Magnetic Needle," by the Rev. S. J. Perry, F.R.S.

Linnean Society, June 15.—Prof. Allman, president, in the chair.—Prof. Rolleston read an interesting paper on the prehistoric pig of Britain, illustrating this by a series of skulls of species, wild and tame.—Dr. Masters followed by remarks on the superposed arrangement of the parts of the flower. The alternate arrangement in the parts is so general that exceptions are invested with peculiar interest. "Alternate" and "superposed" the author used in preference to the term "opposite," and he stated superposition exists in a large number of very diverse families. He then gave instances of apparent or false superposition in certain of the cultivated varieties of Camellia, &c. Real superposition may arise from (1) superposition of whorls, exemplified in the monstrous Daffodil (*Narcissus Eystettensis*; (2) spiral arrangement of parts, *e.g. Sabia*; (3) enation, chorisis, between which it seems necessary to draw a distinction, although the differences in the adult flower may not be always obvious (in chorisis the original organ is repeated, in enation the process is subsequent to the first stages of development, example scales before the petal in *Silene*); (4) abortion or suppression of intermediate whorls, *e.g*, Vine, &c.; (5) pleiomery, when numbers of successive whorls are unequal, some of the additional parts become superposed *Nigella* cited; (6) substitution of one organ for another, in *Zanthoxylum*; (7) torsion of the axis, either between two successive whorls or of constituent elements of whorl, exemplified in leaves rather than flower.—Dr. Masters then drew attention to illustrations of the relative position of the perianth and andrœcium in genera of the *Ulmaceæ* and *Olacaceæ*.—A paper by Dr. J. Anderson on the skeleton and feathering of the spoon-billed sandpiper (*Eurynorhynchus pygmaeus*) was read, and Mr. E. Harting in exhibiting skins of this rare Indian bird and its allies, made remarks thereon. Dr. Anderson shows that, excepting deviation in the bill, *E. pygmaeus* in detail agrees with the genus *Tringa*.—Mr. W. Archer gave a summary of a paper of his on the histology and development of the genus *Ballia*. The material for research was furnished partly by the *Challenger* and partly by the Transit of Venus expeditions, and obtained in Kerguelen's Land. The author found that the septa separating contiguous cells contained circular "pits" which were closed by plano-convex "stoppers," the purpose of which is difficult to determine. The pits do not communicate and the pair of stoppers, easily disturbed from their positions, resemble a rivet passing through the septum. He further described the peculiar manner in which the cells of the rachis are jointed together, the mode of development of the branches, the origin of the cortical investment of confervoid filaments, and tantamount modifications in nearly-allied species.—A second communication of Mr. Archer's was on fresh-water algæ collected

by Mr. Moseley in Kerguelen's Land.—Prof. Duncan then delivered an oral epitome of a joint research by himself and Major-General Nelson, R.E., on some points in the histology of certain species of Corallinaceæ. Quekett, about 1851, gave a good account of the minute textural peculiarities of the hard structures of corallines generally, and in 1866 Rosanoff published a memoir on the Melobesiæ, therein bringing to light many details of the softer structures omitted by the former. Major-General Nelson and Prof. Duncan now supplement the foregoing by further microscopic investigations on the living forms of Bermuda and Britain. On the shores of the former island the high and constant temperature conduces to a development and growth of the corallines not witnessed on our own sea-board, and the colours, moreover, are rich in proportion; for these and other reasons a more complete study of their development and physiology has been made. Starting from Quekett's and Rosanoff's labours, the recent researches show the presence of remarkable filamentous appendages to the dermal layer, which latter is composed of a loose cellular envelope, permitting the existence of large sub-dermal areas. The interior more aggregated cellular substance has certain radiating fibres running through, and which are modified at the joints. The growth of the cell-structure, semilunar bodies developed in the primordial utricle, the manner in which the deposition of carbonate of lime takes place, and other interesting facts, the authors elucidate and place on record. —Mr. R. B. Sharpe, in exhibiting a collection of birds from South-east New Guinea, collected by the Rev. S. McFarlane, and now deposited in the British Museum, pointed out that most of the forms had already been obtained by former travellers, though one species, *Graucalus augustifrons*, was new to science, as probably was a Bird of Paradise, so injured, however, as to prevent a correct description being made. The nest of a Bower-bird was also commented on.—A memoir on the Oxystomatous crustacea, by Mr. E. I. Miers, was taken as read, also two papers on New Zealand Ferns, by Mr. J. H. Potts; and notes on algæ collected by Mr. Moseley, of the *Challenger* Expedition, by Prof. Dickie; besides a paper by the Rev. J. M. Crombie, on lichens from the Island of Rodriguez, obtained by Dr. I. B. Balfour, 1874.—In an additional note relative to the Norwegian Lemming, Mr. W. Duppa Crotch referred to some recent information obtained supporting his formerly expressed views.—In the form of an oral abstract, Mr. S. H. Vines gave a lucid account of some late experiments and chemico-physiological investigations of his into the nature of the digestive ferment of *Nepenthes*. In the Pitcher-plant, at least, he pretty clearly proves that a secretion and other phenomena equivalent to the digestive process of animals obtains.

Anthropological Institute, June 27.—Col. A. Lane Fox, F.R.S., president, in the chair.—The election of two new members was announced.—Mr. Walhouse exhibited arrow-heads from Southern India, closely resembling forms met with by Lieut. Cameron in Central Africa.—Remains of red deer, wolf, with portions of a human skull, from the foundation of the Bath gas-works, were exhibited by Miss A. W. Buckland.—Mr. Hyde Clarke read a paper on serpent and siva worship and mythology in America, Africa, and Asia. The first part of the paper was devoted to an account of the Bribri and other Indians of Costa Rica in Central America, and of the immediate relations of their languages to those of Western Africa. This furnishes another connection of language besides the Carib with the Dahomey, the Guarani with the Agan and Alkhass, and the Quichua, Aymara and Maya, with Accad and Cambodian. The rest of the paper was devoted to trace the Central American one god Sibu, and his mythology to the old world. This word, as Sowo and Nebo, is in company found with Kali in West and Central Africa, over a wide area, representing god, spirit, idol, navel, &c. It was then illustrated with Siva and Kali, and the cosmogony and serpent worship in India; and further with Nebo in Babylonia, Seb in Egypt, Seba in Arabia and Phrygia. The title Sabaoth was referred to. The American legend appeared to point to a unity of God in the prehistoric epoch.—Mr. Park Harrison described marks found last summer on the chalk at Cissbury, some upon the walls of the galleries, and the remainder on rounded pieces of chalk.—Dr. Gillespie read a short note on the use of flint cores as tools.—The remaining papers were "on the term Mediterranean," as applied to a part of the human race; and a minute account of the Javanese, Mr. Kuhl.

Physical Society, June 24.—Prof. G. C. Foster, president, in the chair.—The following candidates were elected members of the Society:—Prof. James Dewar, F.R.S.E., and the Hon. F. A. Rollo Russell.—Prof. Guthrie showed the action of Prof. Mach's apparatus for exhibiting to an audience the effect of lenses on a beam of light passed through them. It consists of a long rectangular box with glass sides, in which are several movable lenses. A parallel beam of light falls on a grating at one end of this box and is thus split up into a number of small beams, which are rendered visible by filling the box with smoke. After passing through the first lens the rays fall on a movable white rod, which may be placed to indicate the focus. The light then falls on another lens partly covered with red and partly with blue glass in order to more precisely exhibit the paths of the rays.—Baron Wrangell exhibited the apparatus employed by Petrochovsky in his magnetic experiments. These experiments had reference to (1) normal magnetisation, (2) the measurement of the distance of the poles of a magnet from its ends, and (3) a thermo-electric apparatus. The determinations were very much simplified by employing a unipolar magnetic needle, formed by bending a small bar magnet at right angles at about a quarter of its length from one end. The needle is then suspended by a fibre attached to the end of the short arm, and the longer arm is maintained horizontally by a brass counterpoise weight. It will be evident that as one pole is in the axis of rotation, it cannot have any effect on the motion of the needle. By turning up each end in this manner the moment of the magnet may be ascertained without knowing the exact positions of the poles. If a magnetic needle be so placed that a bar magnet parallel to it has no effect in deflecting it from the meridian, and the bar be then struck with a brass hammer, the state of equilibrium will be disturbed, as is shown by the motion of the needle. This, however, is not the case with a piece of soft iron round which an electric current is passing. The apparatus employed in the experiments on "normal magnetisation" consisted of an arrangement for passing a current round rods of soft iron of varying lengths, so constructed that any number of the surrounding coils can be removed in the manner of an ordinary rheostat. After the current has been passed round the bar, it is moved until its residual magnetism has no effect in deflecting a delicate unipolar needle from the meridian. The current is then passed round it, and the coils are adjusted until the magnetised bar has still no effect on the needle. The effect of the coils themselves is counteracted by means of a subsidiary coil. When the current is thus adjusted, the bar is said to be "normally" magnetised, and M. Petrochovsky has ascertained that this condition is satisfied when the length of the coil is 0·8 times that of the bar, and this is independent of the strength of current. This, then, is the only case in which the position of the poles is the same as when the bar is charged with residual magnetism. For the determination of the positions of the poles of a bar magnet a somewhat complicated apparatus was employed. A large unipolar magnet about eight inches in length, provided with a bifilar suspension, was enclosed in a glass box. A fine silver wire was stretched parallel to the axis of the needle between two projections on it, and it also carried a fine index at the horizontal end. The wire is focussed in a telescope which can be made to travel along rails parallel to the magnet, and the index at the end can be observed by another telescope. A small magnet at right angles to the large magnet can be moved with the first telescope, and the point at which its effect in deflecting the unipolar is the greatest is ascertained by varying its position parallel to itself along a graduated scale and then observing the space through which a subsidiary magnet must be moved in order to restore the unipolar to its original position, as observed in the second telescope. When this point is reached it must be exactly opposite the pole of the large magnet. It was thus found that the poles are at a distance of one-tenth of the length of the magnet from its ends. To determine the position of the poles of a horse-shoe magnet a delicate magnetic needle is placed below a fine wire in the meridian and a horse-shoe magnet is brought so that its two ends are immediately below the wire and near the needle. In the case of an electro-magnet the point at which its effect is greatest is found to vary when the coils are moved towards the ends, and is nearest to the ends when the coils project slightly beyond them. The third series of researches referred to was on the influence of an electric current on the thermo-electric action of soft iron. A number of strips of iron are connected by means of copper studs, and when currents are passed round the alternate strips it is found that the system acts as an ordinary thermopile. This question is, however, still under investigation. In reply to a question of the President, Baron Wrangell stated that the effects of increasing the number of coils in the horse-shoe

magnet on the position of the poles is also still under investigation.—Prof. Barrett then made a brief communication on the magnetisation of cobalt and nickel. He has recently made some experiments on these metals with a view to ascertain whether they undergo any elongation or contraction similar to that experienced by iron during magnetisation. From this first experiment he concluded that cobalt elongates slightly, but that there is no effect on nickel, but this latter result may have been due to the fact that the metal was not absolutely pure. He has, however, obtained through Mr. Gore a fine bar of pure nickel about two feet in length, and now finds that it contracts, and that the amount of this contraction is about the same as the expansion of a like iron bar when similarly treated.—Prof. Guthrie then described some experiments on the freezing of aqueous solutions of colloid substances, which he has been studying in connection with his recent investigations on cryohydrates, &c. If a solution of sugar be gradually cooled the temperature at which ice separates out is always below 0° C., and the extent below increases with the amount of sugar in solution; but he finds that in a solution of gum having exactly the same chemical formula, the ice always separates at 0° C., whatever be the amount of gum present. Thus while every crystalline substance forms a freezing mixture when mixed with ice or snow, colloids are incapable of doing so. The gum and the water do not recognise each other: and similar results were obtained in the case of gelatine and albumen. These facts are strictly in accordance with the results of Prof. Graham's classical researches. It almost follows that, when heated, similar effects are observed, and Prof. Guthrie has found that solutions of gum in varying proportions always boil at 100° C. Mr. W. Chandler Roberts said that this important discovery was one that his late distinguished master would have welcomed, and he expressed a hope that Dr. Guthrie would continue his experiments with the series of colloids actually prepared by Graham.—Prof. Guthrie then showed the experiment by which Dr. Kerr has recently proved that glass, resin, and certain other substances exhibit a depolarising effect when under the influence of a powerful electrical tension. With the help of Mr. Lodge, Dr. Guthrie has succeeded in repeating these exceedingly delicate observations, but the effect is very slight and ill-suited for the lecture-room. A beam of polarised light traverses a thick plate of glass in which two holes have been drilled nearly meeting in the centre, and two wires are fixed in these and connected with the terminals of a powerful coil. The light after passing through the analyser falls on the screen. If now the analyser be so turned that the illumination is least before the current is turned on, the brightness of the field will be seen to increase as soon as the circuit is closed, and this brightness will increase up to a certain limit. The effect is greatest when the light is polarised at an angle of 45° to the line joining the terminals.—The President then adjourned the meetings of the Society until November.

PARIS

Academy of Sciences, July 3.—Vice-Admiral Paris in the chair.—The following papers were read:—On the fermentation of urine, by MM. Pasteur and Joubert. The ferment of urea, M. Musculus considers of the class of soluble (and not organic) ferments. The authors affirm that his soluble ferment is produced by the small organic ferment of urea.—Observations on M. Pasteur's communication, and on the theory of fermentations, by M. Berthelot.—Reply by M. Pasteur.—Note on M. Cros' paper regarding photographic reproduction of the colour of bodies, by M. Becquerel.—On the carpellary theory according to the Amaryllideæ (third part: Galanthus, Leucoium), by M. Trecul.—Third note on electric transmissions through the ground, by M. du Moncel. The currents due to difference of humidity in the ground about the plates arise through difference in facility of oxidation. Those due to unequal extent of surface of the plates arise because the electric action from physical contact of two heterogeneous bodies varies with their surface of contact, and because oxidable bodies are more attacked when they present a small surface to oxidation, than when they present a large.—Examination of new methods proposed for finding the position of a ship on the sea (continued), by M. Ledieu.—New series of observations on the protuberances and solar spots.—Letter from R. Secchi (June 28). A table is given for the first six months of 1876. Few protuberances; hardly any eruption; threads of gas rising straight and vertically, and of short duration. The issuing hydrogen seems to push aside the darker layer of absorbing metals, and thus produce very small faculæ. Since March almost no spots with nucleus and penumbra. Maxima of activity in latitudes 10° to 20°, and 50° to 60°.—On a luminous phenomenon at Port Said and Suez, on June 15, by M. de Lesseps. This was a luminous globe which burst like a rocket, with loud detonations.—On the metallic nickel extracted from ores of New Caledonia, by MM. Christofle and Bouilhet.—On the mode of employment of sulpho-carbonates, by M. Jaubert.—Present state of vines subjected to treatment with sulpho-carbonate of potassium since last year, by M. Mouillefert.—Experiments on the destruction of Phylloxera, by M. Marion.—Automatic discharges for electro-atmospheric rods, by M. Serra-Carpi.—On Glaucoma and the climate of Algeria by M. Tavignot.—Studies of astronomical photography, by M. Cornu. Any telescope may be immediately adapted for it by separating the two lenses of the object-glass, by a distance depending on the glass, but rarely more than 1½ per cent. of the focal distance. The original achromatism of the visible rays is transformed into achromatism of the chemical rays necessary for photographic images, and there is no aberration in the images.—On linear differential equations of the second order, by M. Fuchs.—On the isochronism of the cylindrical regulating spiral, by M. Caspari.—On Mr. Crookes's radiometer, by M. Govi.—On the explanation of the motion of the radiometer by means of the theory of emission, by M. de Fonvielle.—On the radiometer, by M. Ducretet.—New peroxide of manganese battery, by M. Leclanché. He compresses strongly a mixture of 40 per cent. of the peroxide, 55 per cent. of retort carbon, and 5 per cent. of gum lac resin. The depolarising mass is thus made to yield more electricity.—Action of hydracids on selenious acid, by M. Ditte.—On the decomposition of insoluble carbonates by sulphuretted hydrogen, by MM. Naudin and de Montholon.—On a new method of substitution of chlorine and bromine in organic compounds, by M. Damoiseau. This is by bringing them together in presence of animal charcoal.—On the synthesis of allantoin, by M. Grimaux.—On a new butylic glycol, by M. Nevolé.—New method of alcoometry by distillation of alcalinised spirits, by M. Maumené.—Researches on fuchsine in wines, by M. Jacquemin.—On nitralizarine, by M. Rosenstiehl.—New mineral contained in a meteorite (daubrelite), by Mr. Lawrence Smith.—On the presence of nickel in ferruginous atmospheric dusts, by M. Tissandier. This favours the idea of their cosmic origin.—Comparative micrographic analysis of atmospheric ferruginous corpuscles, and fragments detached from the surface of meteorites, by M. Tissandier.—On the physiology of the musical apparatus of the grasshopper, by M. Carlet. A special muscle distends the plaited membrane, which thus reinforces the sound. There is no tensor muscle of the timbal, and the two timbals producing the sound vibrate synchronously.—On the toxical action of methylic, cuprylic, œnanthylic, and cetylic alcohols, by MM. Dujardin, Beaumetz, and Audigé.—Anatomical characters of the blood in the anæmic, by M. Hayem. In chronic anæmia the globules are smaller, deformed, and less coloured.—Anæsthesia by the method of intravenous injections of chloral, by M. Linhart.—Lichens brought from Campbell Island, by M. Filhol, determined by M. Nylander.—On a hippopotamus with six lower incisors found in Algeria, by M. Gaudry.—On the morphology of the dental system in human races and its comparison with that of apes, by M. Lambert.

CONTENTS

THURSDAY, JULY 27, 1876

THE UNIVERSITY OF MANCHESTER[1]

III.

IN former articles we have come to the conclusion that the higher education of this country ought to be extended, and further, that this cannot be accomplished by an extension of the powers of the present Universities. The question remains how this can most properly be brought about? Let us, in the first place, refer to those projects that have already come before the public in a manner more or less definite. To begin with the American system. This is one of nearly absolute liberty. A number of men agree together to found an educational establishment, and they obtain, without any difficulty, by application to Government, the power of granting degrees. It can hardly, we think, be said that this system has worked so well in America as to encourage the hope that it may solve the educational difficulties of this country. As a rule American degrees are not highly thought of on this side the Atlantic, and we even question whether many of them command much respect on the other side. The cause of this failure is, we think, to be found in the motives which often induce men to combine together with the view of founding an educational institution. In some cases these are of the most praiseworthy character. The inhabitants of a large and influential district, while they, perhaps, differ from one another in their religious views, are yet convinced of the great importance of the higher education, and agree together to found an institution which is truly unsectarian, and which represents those good things upon which they are all agreed. But in other cases the motives of the promoters have reference not so much to the points on which they agree with the rest of the community as to those in which they differ from it; and in consequence, the institution founded partakes of a denominational character to a greater or less extent. In the one case the institution succeeds; the constituency is a large one; they possess sufficient means, and are enabled to command the services of the most eminent men—chosen only with reference to their acquirements. But, in the other case, the institution is a failure; the constituency being a limited body, is not possessed of sufficient means, and the field from which they must select their lecturers is limited by this as well as by religious considerations. They are, however, able to obtain a charter, but their degrees are of very little value.

It cannot be supposed that the British Government will ever consent to the introduction of such a system; this alternative may, therefore, be dismissed, as we see it has been (very summarily in a foot-note) by the promoters of the Owens College scheme.

The second proposal requires discussion because it appears to have commended itself to some of the leading statesmen of this country. It is the scheme for founding one great examining-board or degree-giving body for the entire country to which the various provincial colleges shall be affiliated. This scheme is alluded to in the following terms in the Owens College pamphlet:—

"Without dwelling on the experience of such systems as that till recently obtaining in France, or contrasting its results with those of systems like the German, it may be remarked that a centralisation of this description is at the present time, and must long remain, practically impossible in England, where neither are Oxford and Cambridge likely to surrender their self-government, nor public opinion to require them to do so."

It is probable that a central board of this nature while confining itself to the province of examination might yet require, unless under exceptional circumstances, the previous training implied in a college education. But even then its faults would be those of the present University of London carried out to their logical climax. At the risk of repeating ourselves we shall again state what we believe to be the faults of such an institution.

In the first place we have the paramount power—that of granting degrees possessed by a body which does not take the responsibility of itself imparting or seeing imparted by others a true education in the complete sense of that word. This education may no doubt be imparted by the various colleges, but the degree is given by a body which is virtually ignorant of the previous educational training of its candidates in a moral and social aspect.

In the next place the degree-examinations, as they are unconnected with any previous class examinations, form only a rough test of the amount of knowledge which each candidate can produce. There is absolutely no attempt to test the quality and excellence of the producing power of each candidate. In fine the moral and social training is not tested, and the intellectual training only imperfectly tested by the central board.

Thirdly, and this is a point of the utmost importance, the Calendar of the Central Board must inevitably embody only the best known and most widely diffused results of knowledge—not that which is growing and plastic, but that which has already grown and hardened into shape—the knowledge in fact of a past generation which has become sufficiently well established to be worthy of this species of canonisation. A very powerful inducement is thus offered to the professors of the various colleges to teach their pupils according to this syllabus, and a very powerful discouragement to attempt to alter it. They may be men of great originality and well qualified to extend and amend their respective spheres of knowledge, but they have no inducement to do so—their interest is to adhere to the syllabus as rigidly as a priest of the Church of Rome adheres to the syllabus of the Pope.

It is the old and time-honoured custom of killing off the righteous man of the present age in order the more effectually to garnish the sepulchres of his predecessors. Our readers are well aware that the natural philosophy course has changed its character very greatly of late years, and, that for this we are much indebted to Professors Sir W. Thomson and P. G. Tait. But could these men have done this under the system of a central board? If they had succeeded it must have been, as Galileo succeeded, against the attempt made by the ruling authorities of his day to stop his voice and strangle his originality.

The next proposal is a modification of this. It does not propose that the system of the University of London should swallow up all other systems, the impossibility of this consummation (however desirable in itself) being recognised. It rather proposes that the University of

[1] Continued from p. [illegible]

London, being a good and desirable thing of which we cannot have enough, should split itself up into two parts — a southern and a northern one—a province of Canterbury and a province of York, and that the various provincial colleges in the north should form members of the great University representing the northern province.

Our reply to this proposal is that believing the University of London to represent an incomplete system we are unwilling to contemplate its universal extension whether this be brought about by the process of absorption or by that of fission.

It is alleged by some who favour this system of grouping colleges together into one University, that a healthy principle of competition is introduced into the teaching departments of the various colleges, and they quote in favour of their views the success of the University of Cambridge in producing eminent mathematicians by this system. We shall here confine ourselves to showing that this supposed analogy is delusive. What the various colleges do, and do extremely well, is to impart a moral and social training to their pupils; but it is well known that in Cambridge the real rivalry as regards mathematical honours is not between the various colleges, but between the various private tutors. The chances are in favour of a certain tutor turning out the next senior wrangler, and accordingly the inmates of the various colleges rush off to this tutor in the hope of gaining the great prize. What this system demonstrates is rather the necessity of a thorough system of tutors in addition to that of professors, in order to secure the high proficiency of a few in any department.

Thus by a species of exhaustion, and by discussing the various alternatives suggested, we come to see that we must look to the various individual provincial colleges to become the future Universities of our country; and the only question that remains is whether Owens College be yet ripe for the change. Let us present the claims of this College to our readers in the language of the pamphlet already alluded to:—

"It remains to inquire whether Owens College may be fairly considered equal to the assumption of such a position, and whether the present period is a suitable one in its history for the College to advance such a claim. The history of the College may in any case be said to have prepared it for a University future. Owens College was founded to provide instruction 'in such branches of learning and science as were then and might be thereafter usually taught in the English Universities,' and it has uniformly sought to pursue a course and maintain a character consistent with this intention on the part of its founder. The support given to it in the district has indisputably been largely given as to an institution desiring to hold an academical level. . . . As to curricula and branches of teaching, the Senate, while unwilling to enter into details, have no hesitation in asserting their opinion that Owens College may, taken as a whole, fairly challenge comparison with any academical institutions of this and with some of other countries. We have here a ready-formed and—in essentials—complete University organisation as regards the Faculties of Arts, Science, and Medicine, together with a newly-formed School of Law. . . . The Faculty of Divinity is indeed absent; but apart from the reasons which, in Owens College as well as elsewhere, have caused its absence, it may be worth observing that the conception of a University by no means involves the necessity that it should possess chairs and grant degrees in all the faculties. This position it would be easy to prove from the history of several Universities of European fame."

This is an era of great educational activity; attempts are being made to reform our great English institutions, and a Commission is at present engaged in discussing the future of the Scotch Universities.

We are convinced that an enlightened government will best complete its efforts in this direction by giving a University Charter to Owens College, not, however, as a last and crowning concession, but rather as the first of a series of concessions, all of which, let us hope, will, when the time is ripe for them, be frankly and graciously made. Let there be no disguising the fact that Owens College is but the eldest of a large and rapidly increasing family, others of whom may, we hope, in the course of time, make their appearance before the state. It may, however, be twenty or thirty years hence before any of the recently established institutions is sufficiently ripe to receive the crowning honour of a University Charter. At present no other college can hope to present similar claims representing something like 500 day students, 800 evening students, and a very large amount of voluntary endowment. This is in truth the work of a generation.

We do not think it probable that any opposition to this movement will arise on the part of the two great English Universities. Their office is rather to lend their distinguished graduates as teachers in these new institutions, and by dint of their own practice and their great influence to see that moral, social, and even physical training are encouraged, as well as training in its merely intellectual aspect. And while they themselves may in the future be probably induced to give a greater prominence to the professorial element than they have yet done, they may in their turn induce the other Universities to encourage the tutorial element to a greater extent. In fine, these two old Universities will, whatever happens, always retain a powerful voice in the educational councils of the nation.

Nor must it be supposed that we advocate the doing away with the University of London, for whatever be the plan adopted there will always be colleges which not having attained to the rank of Universities, must look to that institution as their degree-giving body.

But the function of such an institution is to redress a hardship in the case of pupils rather than to cause and perpetuate a hardship on the part of teachers. The University of London will be heartily welcomed as a channel for imparting a degree that could not othewise be procured, but it ought not to be tolerated as a Procrustean bed for the education of the country. In fine, it was founded as the most available means of redressing a grievance, and for this very reason it is necessarily incomplete.

So long as we continue to progress—so long as colleges multiply and are not yet able to grant degrees,—so long must we retain an institution similar to the present University of London.

AGRICULTURAL WEATHER-WARNINGS IN FRANCE

AN important step has been taken by Le Verrier in the application of meteorology to practical matters by the inauguration of a system of weather-warnings specially designed for the benefit of agriculturists. The

chief features of this system of warnings are briefly sketched in a recent number of the *Bulletin Hebdomadaire* of the Scientific Association of France.

Weather-warnings intended to be useful to the agricultural interest are essentially different from those issued for the benefit of navigation. What sailors require almost exclusively to know is, the force and direction of the wind in approaching storms. On the other hand, what agriculturists require to know is a knowledge of coming rains and of thunderstorms, especially the destructive hail which often accompanies them; whilst the wind, save in rare exceptional cases, little affects them. The ability to foretell rain, the causes of which depend on conditions absolutely different in different parts of France, is unquestionably one of the most intricate problems of science, and therefore demands the closest study, wide knowledge, and sound judgment in working out its successful solution.

When, eighteen years ago, the Paris Observatory, established a system of warnings for the French Marine, the conditions for carrying them out successfully were not known. Now, however, owing to the experience acquired, the observatory is able to issue warnings of so useful a nature, that no serious storm makes its appearance in the Channel, or on the shores of the Bay of Biscay, or of the Mediterranean, which has not previously been announced to the seaports menaced by it. To-day the difficult question of agricultural warnings presents conditions of uncertainty similar to those which warnings for navigation presented in 1858. The present difficulty, therefore, is no reason for doing nothing, but only a reason for greater care and more strenuous exertion. Mistakes will necessarily be made at the first, probably numerous during the first year, seeing that there is still no precise basis on which to rest; they will, however, diminish as experience is acquired, and doubtless the time will by and by come when warnings for agriculture will be attended with a like success as now characterises warnings for navigation.

Agricultural warnings cannot, then, as in the case of warnings for navigation, be issued to the provinces by the Paris Observatory in an absolute form. It is, at this early stage, indispensable that the warnings sent to the chief places of the departments be of a general character to be supplemented and modified by local meteorological experts, who, in doing so, must be guided by their knowledge of the local peculiarities of their particular districts. This mode of procedure will furthermore lead to a thorough examination and a more exact knowledge of the meteorology of France.

The points to be more specially investigated by the departmental Meteorological Commissions at the outset, are these:—1. To follow and investigate the march of the rainfall, not only as regards quantity, but as regards the mode in which it is successively propagated from canton to canton, and from department to department, particularly when, after a season of drought, rainy weather begins to set in. 2. As regards thunderstorms (*orages*), the chief point to be attended to is that information of their first appearance be sent to the chief place of the department in which they occur, which, in its turn, will telegraph the fact to the Paris Observatory, so that the officials there may, in view of the whole circumstances, send timely warnings to those departments which appear to be threatened by the storm. 3. Since little is yet really known of hailstorms, which are often so disastrous to agriculture, it will be necessary to give instant attention to collect such data as may likely lead to some knowledge of the influence of woods, hills, and river-courses on the origin and progress of the hailstorm. 4. In connection with the late frosts of spring, which are productive of such enormous loss to agriculture, the often-alleged effect of smoke in counteracting their blighting influence will be brought to the test of experiment on a large scale, say over the whole extent of a valley. 5. Lastly, warnings relative to inundations cannot but excite the liveliest interest, in consideration of the national disasters of recent years, which might have been to a large extent lessened, if not in many cases averted altogether, if a proper system of such warnings had been in operation. To the civil and mining engineers to whom these warnings have been entrusted, the service of the agricultural warnings will necessarily lend much valuable assistance.

Agricultural weather-warnings began to be issued by the Paris Observatory, on May 1, to the three departments of Vienne, Haute-Vienne, and Puy-de-Dôme, the telegraphic authorities giving the free use of the wires in the transmission of the messages. In order to give a fair trial to this initial experiment the system will be continued daily till October 1, 1876, after which the whole matter will be submitted to a careful reconsideration.

The following example will show the method employed in carrying out the system:—On May 7 the Observatory, to show the general course of the isobarics over Europe, telegraphed that the barometer at 32° and sea-level was 29·607 inches at Palermo, 29·725 at Naples, Florence, Perpignan, and Madrid, 29·922 at Moscow, Berne, Limoges, and Bordeaux, 30·119 at Petersburg, Paris, and Lorient, 30·316 at Helsingfors, Helder, and Greencastle, and 30·512 at Hernösand, and Skudesnes. Attention was further drawn to the fact that pressure was not only high in Sweden, but that it had risen 0·393 inch, and not only low in Sicily, but had fallen 0·196 inch; and that since under this two-fold influence a polar current was flowing over Europe towards the Mediterranean, northern and easterly winds would continue to prevail, bringing with them generally clear skies and, owing to the strong sun-heat, an increase of temperature during the day. This prediction, it is needless to add, was verified by the event.

We most heartily wish every success to this bold and novel system of weather-warnings, designed for the benefit of great national interests. It may be added that it is on a sound practical knowledge of the thunderstorm, considering the term in its widest significance, that the success of these warnings will depend; and it is, therefore, singularly fortunate that in no country has so much well-directed labour and expense been bestowed on the investigation of thunderstorms as in France.

RADCLIFFE'S "VITAL MOTION"

Vital Motion as a Mode of Physical Motion. By Charles Bland Radcliffe, Doctor of Medicine, &c. (London: Macmillan and Co., 1876.)

AS there is a growing conviction of the importance of studying physiology from the side of physics, so we may be led to value more the efforts made in this line

by observers who have for long been content to work on, little cheered by recognition by the great body of physiologists, but finding their reward in honest search after truth.

Among such Dr. Radcliffe has for some years maintained the proposition that the contraction of muscle is not an acquired condition determined by the reaction of a vital property of irritability with certain stimuli, but a natural condition resumed after the removal of an electrical charge by which extension had been previously effected and maintained. In this view, for ideas related to the older terms "vitality" and "contractility," ideas related to electricity and elasticity must be substituted. Again, whereas the electrical phenomena manifested in muscle and nerve have been generally regarded —notably by Du Bois-Reymond—as phenomena of current electricity, Dr. Radcliffe has held that so far as they are functionally important, they are phenomena of static electricity, of charge and discharge.

This contention is once more set before us in the book just published under the title heading this notice, with many new arguments and with several material changes in the interpretation of facts.

In former papers Dr. Radcliffe imagined muscle and nerve to be charged with electricity after the manner of a Leyden jar; the coat (neurilemma or sarcolemma) of each fibre doing the work of a dielectric. Many serious difficulties opposed the acceptance of this notion, and now another, certainly much more accordant with the facts, is substituted. According to this later notion, the condition of each muscular or nervous fibre while alive and at rest is one and the same with that of an electromotive element, such as a Daniell's cell, in the state of open circuit. In the polarity of the electromotive element is found the explanation of the apparent existence of a current running from longitudinal to transverse or cut surface, in mutual repulsions of molecules charged with electricity, the explanation of the lengthening, after contraction, of fibres at rest; in variations of electrical charge, and in hypothetical closures of circuit the explanation of the contraction of muscle, of the return of a perfectly elastic substance to the form from which it had been distorted by the charge. Dr. Radcliffe argues that the instantaneous extra and induced currents set up at the opening and closing of circuits are important agents in discharge, and that such instantaneous currents "may be through inductive interaction greatly intensified and might prove to be very powerful" if they were not in great measure lost by being "short-circuited" within the body. As regards the mode in which circuits may be closed and nerve-muscle discharge caused by the will no clear explanation is set forth, though it is remarked that "there is no difficulty in believing that electricity, the slave of the will in this case, may have been ordered out of the way" and muscular electricity left to its own devices.

This theory of nerve-muscle charge and discharge finds important outcome in the book, having application to inhibition, rhythmical movements, rigor mortis, the influence of artificial electricity on vital motion, the work of the blood in vital motion, and many reactions of disease. The chapters relating to these are all most interesting and full of valuable suggestions, but our space will not allow of any analysis of them. A chapter on the "Electrophysics of Vital Motion" demands however a few remarks. Here are recorded observations on the electrical condition of living protoplasm, and here are made inductions to the following effect: (1) that there are no more indications of intrinsic development of electricity in vessels containing living protoplasm, of amœbæ and the like, than in vessels containing distilled water; (2) that living and lifeless bodies are equally under the sway of an electrical potential which varies from hour to hour, so that they are differently charged from hour to hour; (3) that charge will produce expansion which will be greater in aëriform bodies than in bodies which are fluid like water, and greater in these latter than in bodies which are of the nature of solids; (4) that the expansions will operate unequally in bodies which (like amœbæ) are made up unequally of portions which are more or less solid, and portions which are more or less liquid.

Amœboid movements are therefore, "as far as their electrophysics are concerned," the results of variations of electric potential. The parenthesis is important in freeing the author from the charge of forgetting that there may be other forces at work. Granting even that "electric potential" may mean the sum of the operation of a number of cosmical influences—of heat, of gravitation, of lunar and planetary perturbations; all extrinsic, all varying at any point from hour to hour—and this is granting a great deal—there are still left to be considered all the intrinsic influences which may affect molecules and determine movement, such as osmose, chemical affinity, colloid dynamis, and the like. Dr. Radcliffe's colligation is as follows: certain movements are observed to take place in small bodies composed of a mixture of semi-fluid protoplasm with more solid matter; it is conceivable that variations of electrical charge may affect these unequally and produce movement; certain variations of electrical potential are going on at the same time and in the same place in which the bits of protoplasm are moving; the bits of protoplasm do not generate or possess independent or original electricity; therefore the movements are probably produced by the variations of charge consequent on the variations of potential. Surely much more than the "hint" which the author finds in the coincidence is necessary for the establishment of wide inductions.

Fortunately the position taken with reference to the "electrophysics" of nerve and muscle rests upon a much firmer ground of observation and inference. The position is worthy of attentive study, and the argument generally commends itself to our acceptance. At least it invites further examination, and offers many possibilities of proof or trial by collateral observation. We may confidently hope to see the original and acute reasoning of the author generally acknowledged, and, better still, justified and amplified by future followers and observers. W. M. O.

FEISTMANTEL ON THE BOHEMIAN COAL BEDS

Studien in Gebiete des Kohlengebirges von Böhmen. Von Mdr. Ottokar Feistmantel. (Prag, 1874.)

AMONG the additions which extended research is every day making to the stock of our geological knowledge, none are perhaps so welcome as those which

enable us to bridge over the gaps and fill in the blanks which are unfortunately at present so numerous in the geological record. The work that has been done in this direction of late on the borderland between the Carboniferous and Permian formations promises before long to be productive of very important results. Even in so small an area as Great Britain the order of events that happened between the depositions of these two groups must have varied very much from place to place, as will appear from the following table, in which some of the more important sections are shown in a condensed form :—

North Staffordshire	South Yorkshire.	Lancashire.	Cumberland.	Ayrshire.
Permian.	Permian.	Permian.	Permian.	Permian.
POSSIBLE PASSAGE.	STRONG UNCONFORMITY.	UNCONFORMITY.	UNCONFORMITY.	UNCONFORMITY.
Upper Red* Coal-measures.	Wanting.	Upper Red* Coal-measures.	Wanting.	
	Red Rock of Rotherham.†		Whitehaven Sandstone.†	Red Sandstones.†
	UNCONFORMITY.		UNCONFORMITY.	STRONG UNCONFORMITY.
Middle Coal-measures.‡	Middle Coal-measures.‡	Middle Coal-measures.‡	Coal-measures.‡	Coal-measures.‡

* With few coals. † With coal plants. ‡ With thick coals.

Whatever be the value of the identifications ventured on in the above table, it serves at least to establish one fact; that, in the interval which it covers, there are at some spots two stratigraphical breaks, at others only one, and at others, perhaps, none at all; for in the North Staffordshire instance it is very likely that we have not a mere case of deceptive conformity, but may be a true passage. There would be nothing strange in this if we were dealing with the equivalent deposits of the whole world, or even of a large continent, but the fact that such a variety of changes went on within so small an area is worth notice, for it shows how variable were the physical conditions of what may be called the Permo-Carboniferous period; suggests to us that its oscillations, important as they are locally, may have been only local; and so paves the way for a favourable reception of any fresh discoveries that point to an absence of any break between these two formations, which are with us for the most part so sharply marked off from one another. And indeed our home experience is quite sufficient to suggest the possibility of such cases turning up; setting aside the North Staffordshire instance, which is not beyond question, the general lithological character of the Upper Coal Measures and their markedly red colour seem to point to a commencement of what may be called Permian conditions before the close of the Carboniferous period, and to establish something of a bond of union between the two formations, in spite of the unconformities which locally separate them. And when we go beyond our home circle we soon meet with cases where a passage from Carboniferous into Permian seems to exist; such, for instance, as those described by Dr. Dawson in Nova Scotia ("Quart. Journ. Geol. Soc." xxx. 209), and by Dr. Toula in Spitzbergen ("Leonhard and Geinitz' Jahrbuch," 1875, p. 225). In the monograph before us, Dr. Feistmantel treats of what he believes to be a similar instance in the coal-fields of Bohemia.

The coal-bearing beds of that country and their associated strata are broken up into a number of detached basins, and the exact correlation of the members of the different patches is, of course, open to some uncertainty; but Dr. Feistmantel thinks he can establish the following general order of succession, and three main sub-divisions :—

C. { Red sandstone, with *Araucarites Schrollianus*.
Strata, with Carboniferous plants.
Bituminous shale (Schwarte), with fish; very few indistinct traces of plants.

B. { Strata, with Carboniferous plants.
Gas-shale of Nurschaw, fish, and abundance of Carboniferous plants.
Strata of Radovenz, with Carboniferous plants.
Red sandstone, with *Araucarites*, on the north-east Bohemian Basin.

A. Strata, with Carboniferous plants.

Of these sub-divisions, A yields 232 reputed species of plants, of which 101 pass up into B; all are species usually looked upon as Carboniferous. But as we ascend in the measures, there is a gradual decrease in the plant remains, specially among the arborescent forms, which disappear in the Upper Permian, Stigmaria Ficoides alone surviving to the last. The animal remains of A are five in number and rare: they comprise a scorpion and spider, a grasshopper, and two crustaceans; all are confined to the group.

Among the beds of the groups B and C the author lays special stress on the gas-shale of Nurschaw and the Schwarte, the animal remains of which he describes as characteristic Permian forms ("exquisit permische Thierreste"), and he infers from the intercalation of these beds with others containing only Carboniferous plants, that no hard line can be drawn between the Permian and Carboniferous formations. This conclusion, to say the least, rests on somewhat slender evidence; the genera of fish quoted in his lists, on which we must mainly rely, are only seven in number, and the species are determined in four cases only; of these, one comes from a deposit the Permian age of which may be admitted, some from beds reckoned Permian by some authors and Carboniferous by others, and some genera are common to both formations. Such an amount of evidence can scarcely be accepted as conclusive. There is also a little inconsistency in the

author's final results; after having, to his own satisfaction at least, broken down the old land-marks, he proceeds to establish new ones where, according to his own showing, no hard and fast lines exist; he classes the group C as Lower Permian, A as Carboniferous, and parallels B with the Ottweil beds of the Saarbruck coal-field, which by the way are distinguished by the absence of Permian forms. It is further a matter for regret that so painstaking an observer has so little of the gift of lucid arrangement, and that he indulges so largely in what De Quincey calls the carpet-bag treatment of sentences.

But faults like these will not detract from the real value of the work; when the time comes for a rectification of boundaries on the Permo-Carboniferous frontier, the vast mass of carefully-observed facts which it furnishes will form no unimportant contribution to the body of evidence by which the question must be decided. The author may have been premature in his conclusions, but his industry and application have produced a work that will have a permanent value. A. H. G.

OUR BOOK SHELF

Holidays in Tyrol—Kufstein, Klobenstein, and Panveggio. By Walter White. (London: Chapman and Hall, 1876.)

THIS volume may be regarded as the complement to that published a good many years ago by Mr. White, "On Foot through Tyrol," in which the Brenner was the eastern limit. The present one takes us to south-east Tyrol, occasionally overstepping the boundary that divides Austria from Italy. Mr. White is a leisurely tourist, with no ambition to rival the feats of an Alpine clubbist, but with what may be called an epicurean taste for scenery of all kinds. It is this taste which keeps him to the lower heights, for from such vantage-ground alone it is found can all the varied features of the Alpine scenery be fully appreciated and enjoyed. The volume contains the results of several summer sojourns in southern Tyrol, and while its main feature is pleasant chat about the principal scenes that are presented throughout its length and breadth, there is much interesting gossip about its towns and villages, their antiquities, history, and, above all, about the people, with all sorts and conditions of whom the author came much into contact. He has the faculty of making himself at home and liked wherever he goes a pleasuring, and thus has learned much about the sentiments and ways of the people that an ordinary tourist would never discover. There is no excitement, no sensation, no hair-breadth 'scapes in the book; the chapters are very short, and the reader will feel no difficulty in laying it down at the end of any one of them; but at the same time Mr. White's pleasant chit-chat never wearies, but keeps the reader in a constant state of placidity and quiet amusement. The region described is out of the way of the ordinary tourist, but we should think Mr. White's volume ought to make it popular. The work will form a useful guide to the Southern Tyrol, and is interspersed with occasional notes on geology, which gives it a claim to be regarded as not altogether unscientific.

Angling Idylls. By G. Christopher Davies. (London: Chapman and Hall, 1876.)

MR. DAVIES is already favourably known to anglers and natural history amateurs, and many lovers of healthful and refreshing reading, by his "Mountain, Meadow, and Mere," and his "Rambles and Adventures of Our School Field Club." The present volume contains a number of charming pictures of country scenes and country life grouped round angling adventures. The Idylls—prose in form we may say—are put together with great art, which seldom makes itself felt, are simply told, and full of the unmistakable freshness of "out-of-doors," to use the author's synonym for Nature. To a jaded mind they will be found almost as refreshing as a day by a river side with rod and line is to a jaded body. Mr. Davies has a good knowledge of natural history, and knows how to observe and tell what he sees, and both the botanist and zoologist will find something to interest them in the book. Under the title of "Angling Acquaintances" he describes graphically the habits of the otter, water-vole, heron, and other animals to be found in the neighbourhood of water, and does the same in another chapter for "Waterside Plants." For lovers of the country and especially of the gentle craft the book possesses many attractions.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.]

Extreme Temperature of Summer

ON Saturday, July 15 last, the temperature (in the shade, four feet from the ground) at the Royal Observatory, Greenwich, rose to 93°·0; on Monday, July 17, to 94°·0; and on Saturday, July 22, to 90°·2.

Since the establishment of the Magnetical and Meteorological Observatory in the year 1840, higher readings than 94°·0 have been recorded on two occasions only; 94°·5 in 1858, June 16, which was very early in the year for so high a temperature; and 96°·6 in 1868, July 22.

The following further particulars collected from the Greenwich records may interest some of your readers.

It appears that the temperature has risen to or above 90°, out of thirty-six years, in twelve years only. The annexed list gives the particular days on which such extreme temperature was shown:—

		°			°
1842, Aug.	10	90·5	1868, July	20	90·0
1846, June	20	91·1	,, ,,	21	92·2
,, July	4	91·8	,, ,,	22	96·6
,, ,,	5	93·3	,, ,,	28	90·1
,, ,,	31	91·3	,, Aug.	5	90·5
,, Aug.	1	92·0	,, Sept.	7	92·1
1852, July	5	90·3	1869, July	22	90·9
1857, June	28	92·7	1870, June	22	90·2
1858, ,,	16	94·5	1872, July	25	90·9
1859, July	12	92·5	1874 ,,	9	92·0
,, ,,	13	92·0	,, ,,	20	91·8
,, ,,	18	93·0	1876 ,,	15	93·0
,, Aug.	25	91·3	,, ,,	17	94·0
1868, July	16	92·0	,, ,,	22	90·2

The years 1846 and 1868 were remarkable for high summer temperature; in 1846, 91°·1 was registered as early as June 20, and in 1868 92°·1, as late as Sept. 7.

Throughout the whole period of thirty-six years, the *earliest* summer maximum occurred in 1862, on May 6, and was 81°·5. The *latest* summer maximum occurred in 1875, on Aug. 16, and was 85°·4. The year 1860 was remarkable for depressed temperature; the highest summer reading having been 75°·0 only, on July 17. The year was one which agriculturists will well remember. It was in violent contrast to 1859, as the table above given shows.

Selecting the highest recorded temperature in each year, from 1841 to 1876, with the day of its occurrence, it appears, on the average of the thirty-six years, that the mean of such highest readings is 88°·3, the corresponding mean day of occurrence being July 11. WILLIAM ELLIS

Royal Observatory, Greenwich, July 24

Earthquakes in Samoa

DURING the months of December and January last there was much local seismic disturbance on the north side of the island of Savaii. Loud underground reports were heard in one particular spot near the coast. They were at irregular intervals, but

were sometimes very frequent. I could not ascertain from any of those resident in the neighbourhood the exact number in any definite time, but for several days they must have been almost hourly. The concussion was felt for a distance of four or five miles only around the focus of action; but it was so severe in the nearest village, that the people deserted their homes during its continuance.

On February 1, at 4.30 P.M., we had a very long shock of earthquake, which was felt all over the group. It lasted within a few seconds of two minutes. The oscillation was very great. The islands seemed to be in the hands of Mafui'e (the earthquake god), and he shook us with a vengeance. I took my watch in hand when I felt the first indication of an earthquake, and sat for a minute amidst the clatter of windows, lamp-glasses, and everything movable (a gentleman writing to me about it next day said his house seemed turned into a factory, with the clatter of machinery), but as it appeared to increase in severity, I deemed it prudent to go outside the house. I then noticed that the thatched roof presented the appearance of waves running rapidly across from south to north. After it was over I found two clocks—one facing north, the other south—had been stopped; one facing west was still going. In three parts of my house the plaster at the angles of walls had been broken down. Bottles were thrown down and broken. In my study, books on a shelf facing north were shaken forward; those on shelves running north and south were not affected. The screw of a copying-press, which I had used just before the earthquake, and which was standing up at the time, had been run down. I found by experiment afterwards that it required a vigorous shake with both hands for half a minute to make the screw run down.

Immediately after the earthquake I went to see if there was any oscillation of the sea. There was nothing perceptible on this—the north—side of the island. I have learned, however, from various sources that there was much oscillation on the south side. Directly after the shaking was over the reef was seen to be bare, and fish were lying exposed on it. The natives rushed to secure the fish, and while they were busy picking them up they were overtaken by a wave, which would have proved fatal to many had they not been expert swimmers. I have heard of only one life lost—a child, who was found next day jammed between two masses of growing coral. It was low water at the time, but low-lying villages were flooded by the wave.

During the following night we had four slight shocks of earthquake, but have had nothing severe since.

Upolu, Samoa, April 3 S. J. WHITMEE

P.S.—I wish to correct a misprint in my letter on "The Degeneracy of Man," which appeared in NATURE, vol. xii., p. 47. In speaking of the language of the Polynesians, I said there are many refinements, a large proportion of which are *un*known to most of the present generation. *Unknown* is, however, printed *known*, and thus the point of the illustration is lost.

Fauna and Flora of New Guinea and the Pacific Islands

I HAVE just read, with very great interest, some anthropological and zoological notes on a trip up the "Fly River" in New Guinea, by Signor D'Albertis. From these notes it appears that the "heaps of dung" which have been supposed to indicate the presence of a rhinoceros in the island, are probably the excrement of the Casuarius. Signor D'Albertis also reduces the "tracks of buffaloes" to those of wild hogs; and the fabulous bird "with a spread of wings of 16 feet" (which, in a former letter, I conjectured might have been a Casuarius, with proportionately large wings added by the imagination of the explorers under the influence of excitement), turns out to be nothing more than a *Buceros ruficollis* with a spread of wings of "4 or 5 feet."

We have, therefore, no reason for modifying our views as to the relation which the fauna of New Guinea bears to the rest of the world. Signor D'Albertis mentions a few examples only of the New Guinea flora, but some of these are specifically identical with common South Pacific Island plants.

In connection with this subject, it may be interesting to some of your readers to know that I have just entered into an arrangement with a Danish botanical collector—Mr. Fritz Jensen—under which he will start from Samoa during the present month on a voyage through the Union, Ellice, and Gilbert Islands (Atolls), to collect for me in botany and zoology. On his return to Samoa in July, he will accompany me to the Loyalty Islands, where he will make a stay of four or five weeks collecting chiefly in botany. At the close of that period Mr. Jensen will proceed to the south-east coast of New Guinea (I have some hope of accompanying him), where he will spend about two months collecting.

Mr. Jensen has been residing with me for several months working at the Samoan flora, of which I have about 700 species in my collection. By the time he completes his trip I hope the collection will be of some value as material towards the preparation of a Flora of the Pacific Islands. S. J. WHITMEE

Samoa, April 3

Optical Phenomenon

I BEG leave to send you a brief account of a striking atmospheric phenomenon which was visible in this neighbourhood on the evening of the 27th ult. Hoping that some of your usual correspondents from the North of Ireland would have sent you a notice of it before this, I delayed writing to you (see vol. xiv. p. 231).

The phenomenon consisted of a pillar of light which rose vertically from the horizon, over the spot where the sun, then set, presumably was at the time, and reached an altitude of some 8°, or perhaps more. I first saw it about 8.45 P.M., when the sun was set about a quarter of an hour, but it was, no doubt, visible earlier, probably before sunset. As the sun moved under the horizon towards the north, the pillar moved in the same direction, still retaining its vertical position, but becoming gradually lower, until at last it disappeared about 9.40 P.M., the sun being then about 6° 30′ below the horizon. The breadth of the pillar was equal to the apparent diameter of the sun. Its colour when first seen was a pale yellow, which as time advanced changed to a golden yellow, and finally to a deep red. The pillar was brighter near the horizon than at a greater altitude, and its upper end was not well defined, but gradually faded away. My son, who was with me, observed that the edges of the pillar were slightly scolloped. The sun had been clear and very hot during the day, but there was a cool air from the north-east, which became colder towards sunset. I have heard that this phenomenon was also visible at Portadown and Tynan, in the County Armagh, and at Aughnacloy in this county.

I presume there can be no doubt that the pillar consisted of a succession of images of the sun overlapping one another, but it is not easy to see how these images were produced. A nearly horizontal stratum of dense air, whose surfaces were slightly inclined to one another, with a rarer medium above and below, might form such a multiple image, by successive reflections and partial refractions at the lower surface, the sun-beam which furnished the direct or principal image to any observer, A, furnishing the second, third, &c., images to observers behind him, so to speak, and sun-beams behind the former, successively furnishing A with the images forming the upper part of the pillar.

I understand that German physicists give this phenomenon the name of Sonnensäule—sun-pillar—and that they have published some speculations as to its origin. I hope some of your readers will kindly contribute information on this subject.

"Felix qui potuit rerum cognoscere causas."

Omagh, Co. Tyrone R. V. D.

P.S.—Since writing above I have learned that the "sun-pillar" was visible over a district of the north-east of Ireland, extending from Portrush in the north to Armagh in the south, and from Bangor (Belfast Lough) on the east to Omagh on the west. I have also heard from two intelligent correspondents that it was visible at sunset, when it attained an altitude of 30°; and from two others that it presented to them the appearance of being crossed by bands, alternately of a brighter and darker shade.

Freezing Phenomenon

I HAVE waited to see whether anyone else would notice a letter that appeared in NATURE, vol. xiv. p. 191, from Mr. Power, under the above heading. Failing such notice, may I point out that the phenomenon to which he refers has already been described. Plumes produced by the crystallisation of water form the frontispiece to Dr. Tyndall's Lectures on Light (Longmans, 1873), and a description of them is given in p. 257 of that volume.

Mr. Power suggests that the brittleness of iron in cold weather may perhaps arise from somewhat similar molecular groupings occurring within the metal whilst it contracts in cooling.

One must, however, recollect that water *expands* when cooled from 39° Fahr. down to the freezing-point. To this the action of cold upon iron affords no parallel, for cold renders the metal more dense. Cold brings the atoms into closer connection; hence cold will (presumably) tend to augment the strength of their mutual attraction. H. M. ADAIR

July 18

Habits of Parasitic Crab

SOME days since I obtained in the trawl a large specimen of the common Ascidian (*A. Virginea*) and kept it alive for about a week. It contained a specimen of the small Parasitic Crab (*Pinnotheres pisum*) about the size of a threepenny piece. The crab came out every night to feed about the floor of the tank, and found lodging during the day, as I afterwards proved by dissection, in the branchial cavity of the Ascidian. The crab is commonly found in the mussel, but I was not aware before that it ever wandered abroad, or sought food except within its tenement. W. S. G.

THE ROWTON SIDERITE

"AN addition of exceptional interest has recently been made to the collection of meteorites in the British Museum, by the presentation, on the part of the Duke of Cleveland, of a siderite (iron meteorite) which fell on his Grace's property at Rowton, near Wellington, in Shropshire, about seven miles north of the Wrekin, on the 20th of April last. At about twenty minutes to 4 o'clock on the day mentioned, a strange rumbling noise was heard in the atmosphere, followed almost instantaneously by a startling explosion resembling a discharge of heavy artillery. There was neither lightning nor thunder, but rain was falling heavily, the sky being obscured with dark clouds for so[illegible] time both before and after the incident narrated [illegible] an hour after the explosion, Mr. George ran[illegible] of Mr. Bayley, had occasion to go to a tu[illegible] occupation adjoining the Wellington and [illegible]ton Railway, about a mile north of the Wrek[illegible] attention was attracted to a hole cut in the gr[illegible]ing the opening with a stick, Mr. Brooks disc[illegible] of metal of irregular shape which proved to [illegible]ite weighing $7\frac{3}{4}$ lbs. It had penetrated to a de[illegible]en inches, passing through four inches of soil [illegible] inches of solid clay down to the gravel—con[illegible]ce of the force of its impact with the earth. [illegible]ich has been protected for further investigati[illegible]rpendicular, and the stone appears to have fa[illegible]uth-easterly direction. Some men were at wo[illegible]t the time within a short distance, and they, together with many other people in the neighbourhood, heard the noise of the explosion."

The above account is taken from the *Wolverhampton Chronicle*, and a further notice is given in the *Birmingham Daily Post* of a meeting of the Natural History Society of Birmingham, at which meeting Mr. Brooks, accompanied by Mr. Gibbons, of Wolverhampton, and Mr. Wills, exhibited the meteorite. Mr. Wills described the circumstances attending the fall, stating that the "sound was heard as of something falling during a heavy shower of rain accompanied by a hissing and then a rumbling noise;" he further stated, "that when Mr. Brooks found the mass it was quite warm." Mr. Wills described it as "being black on the surface, and apparently covered with a scale of metallic oxides; but at the point where it impinged on the earth the oxides had been removed, and the metallic character of the mass had been revealed."

To these interesting and accurate observations, made by the gentlemen of the locality, I have the pleasure of adding that I believe it was very much owing to a resolution passed by this valuable local society, at the suggestion of the gentlemen whose names have been mentioned, to which must be added that of the well-known petrologist, Mr. Allport, of the Rev. H. W. Crosskey, and Mr. Woodward, that Mr. Ashdown, the agent of the Duke of Cleveland, took action in the matter, and obtained his Grace's assent to the meteorite being presented to the trustees of the British Museum.

On its arrival in this department it was with no small pleasure that I found the description of Mr. Wills was in all points accurate. It is, indeed, an iron meteorite, and the special interest of this statement lies in the fact that though our great collection of 311 distinct meteorites at the museum contains 104 indubitable iron meteorites, the falls of only seven of the latter were witnessed.

The collection contains eight stony meteorites that have fallen in the British Islands; but the Rowton meteorite is only the second iron meteorite known as having been found in Great Britain.

It is thus not without a keen curiosity that one inspects a freshly fallen fragment of iron just arrived from space in our own country. One hastens to ask of it what impression the action of the atmosphere has made upon its surface during its brief transit, since most of our iron meteorites have undergone long weathering in the earth. Mr. Wills, however, has given that answer. The meteorite was covered with a very thin pellicle of the jet-black magnetic oxide of iron, and only where this had been rubbed off by abrasion with the soil is the bright metallic surface of the nickeliferous iron revealed. The little meteorite has all the usual appearance of being a fragment. Irregular and somewhat angular in form, with its edges rounded, no doubt, by the fusion and removal of no inconsiderable part of its material in its encounter with the atmosphere, it presents but very slight traces of the finger-and-thumb marks which so characteristically pit the surfaces of most stone and of some iron meteorites. Furthermore, there are fissures which penetrate deeply into the iron mass and bear testimony which there can be no gainsaying to the action of disruptive forces of tremendous strength during the hot encounter of the original mass with the atmosphere, and of which one explosion, and the rumbling echoes, possibly, of others, recorded by the witnesses bear evidence. The form of one of these fissures throws instructive light on the cause of the pitted surface of meteorites. The depth to which the little mass penetrated a stubborn soil is proof of how much momentum still remained to it, partly due, no doubt, to the approximately vertical direction in which it penetrated the atmosphere, and in some degree, too, to the higher density of an iron mass as compared with one of stone, the stony meteorites rarely penetrating to so considerable a depth. This depth of penetration and the direction of the little mass in space near north to south offer close resemblance between this iron and the iron meteorite of Nedagolla, in India.

There are indications on the metallic surface of the composite crystalline structure revealed by etching iron meteorites with acids, and known as the Widmannstattean figures, the results of the separate crystallisation of different alloys, often demarked in some of their surfaces by plates of metallic phosphides.

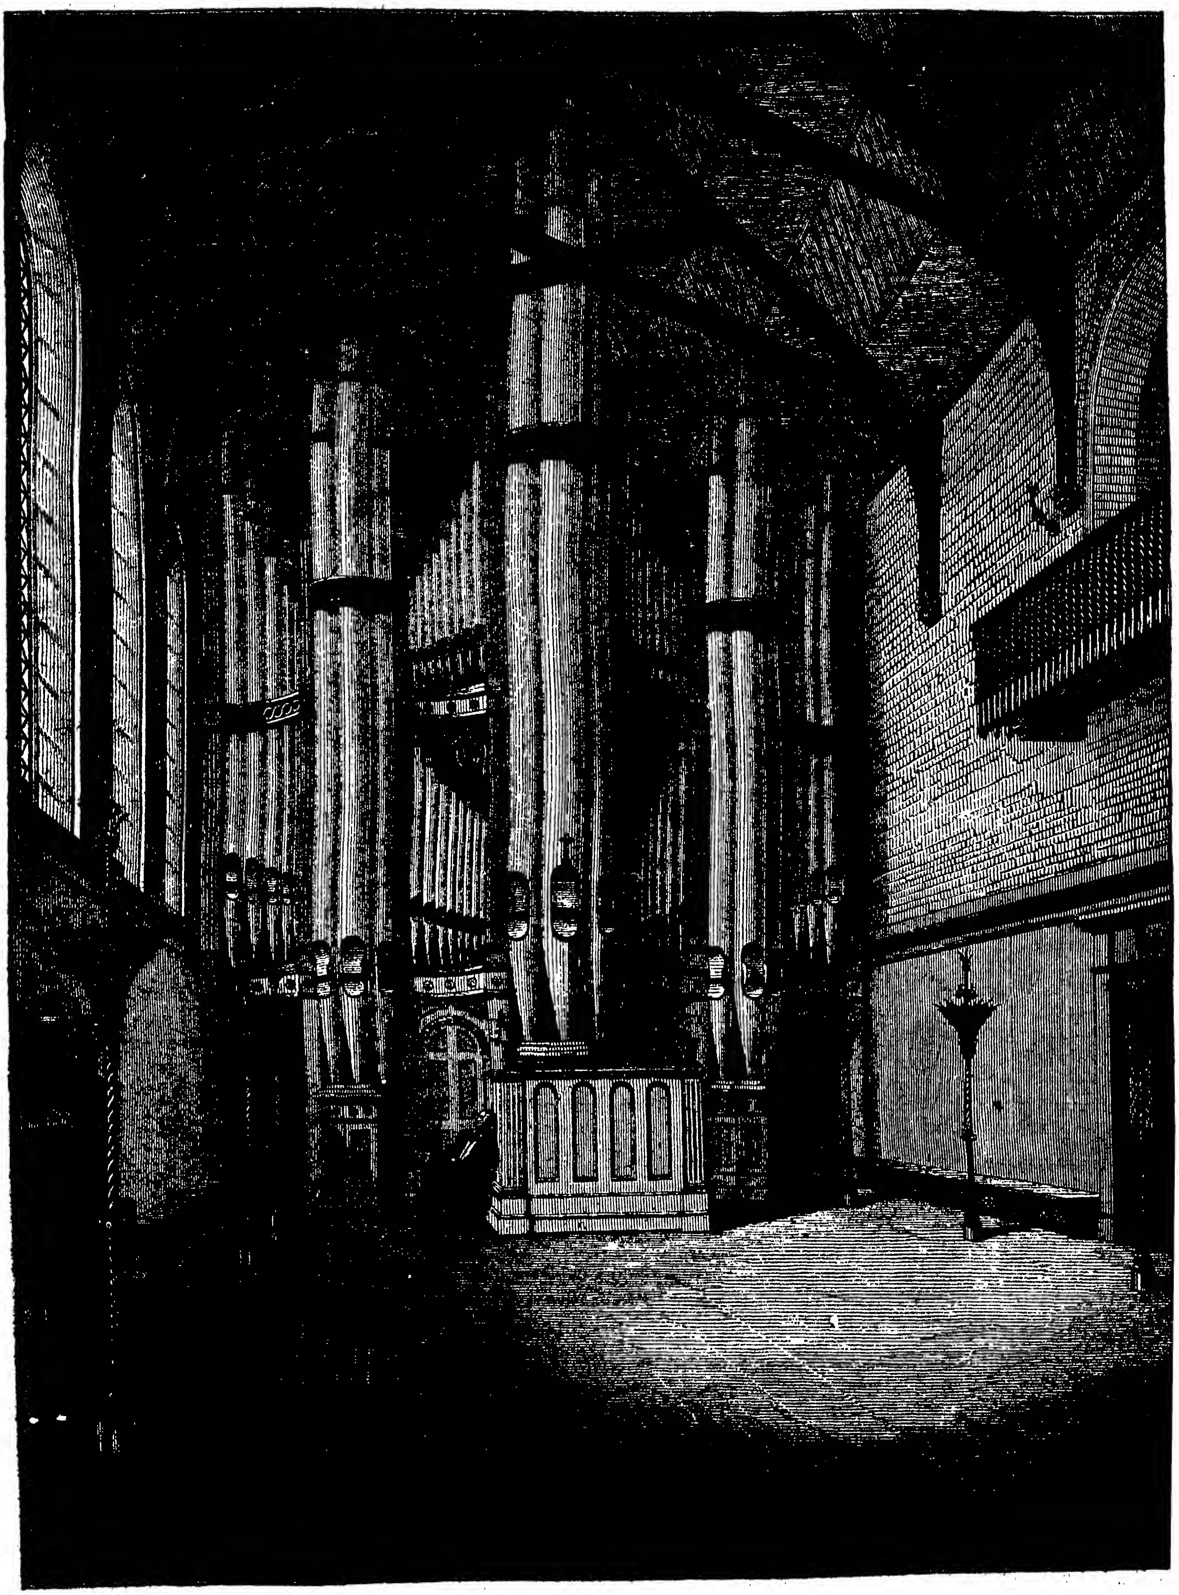
The development of this structure and the consequent determination of the particular type of iron meteorite to which the Rowton siderite belongs, as also the analysis of the iron itself, can only be carried out after a small portion of the meteorite shall have been carefully cut off by the aid of a lapidary's wheel, a process requiring in this particular case some careful precautions to prevent rust being hereafter formed and to reduce the loss of material to a minimum.

N. S. MASKELYNE

A MODERN ORGAN

IT has been hitherto chiefly on the Continent of Europe that connoisseurs in the majestic tones of the king of instruments have had to seek for a grand organ. Though London, the mistress of the world for wealth and magnitude, has churches and chapels innumerable, and organs by hundreds, scarcely one is of sufficient importance or merit to attract the attention of a stranger. Church organs are, as a rule, small, and built without individuality or character of tone, and generally so placed in the building as to effectually mar in acoustical effect any special merit they might otherwise possess. Of the two or three instruments that have any pretensions to magnitude to which the public has access—at the Albert Hall and the Alexandra and Crystal Palaces, no very lasting impression remains upon the audience beyond that of noise and a distressingly harsh volume of sound, utterly devoid of musical depth and grandeur of tone, and quite different from the pleasing reminiscences that dwell upon the memory from hearing some of their more musical Continental rivals at Haarlem, Freiburg, or Lucerne. To successfully construct a large organ is a work of exceeding difficulty, for not only does size greatly complicate the mechanical action, but the proper distribution and apportionment of the wind to each stop, and the harmonious blending of the whole together in the full organ, demands great knowledge and skill upon the part of the builder. It is for these reasons that very few large organs rise beyond mediocrity, or are noted for the beauty of their tone or the perfection of their mechanism. The great advance in the general taste for organ music within the last few years has necessitated an improvement in the mechanical construction of the organ, so as to enable the performer rapidly to command the entire resources of the instrument at will, and give him absolute control over the various sound-combinations and tone-colouring of the different stops, according as they are brought on or off by means of the appliances placed at his disposal.

We give a brief description of the very remarkable organ recently erected at Primrose Hill Road, Regent's Park, remarkable alike for its size, being larger than the great Haarlem organ, its beauty, richness, and grandeur of tone, and the completeness of its mechanism. At present this superb instrument is almost entirely unknown to the musical section of the public. The annexed illustration shows that this organ is one of the first magnitude. It possesses what is known as a 32-feet metal speaking front, with a corresponding weight of tone throughout the pedal organ, and several organs which together constitute the instrument, and give it its place in the scale of magnitude as compared with the more celebrated of the continental instruments. The instrument in question has several novelties not to be found in other organs. It possesses seven distinct organs: pedal, great, choir, swell, solo, echo, and carillon organs, each extending the full compass of 5 octaves (61 notes) with the exception of pedal organ, 30 notes. These various organs are under the control of the performer by means of four manual key-boards, which together comprise sixty-seven speaking-registers, and these are combined together with various acoustical effects by means of thirty-one mechanical movements, making a grand total of ninety-eight sound-controlling registers, worked by hand and foot. The entire mechanical action necessary to control these registers and accessory movements is carried out by a novel application of atmospheric vacuum pressure. Two distinct systems of main air trunks extend throughout the interior of the organ in connection with the wind arrangements situated in the basement of the building. One of these systems of trunks is for the purpose of conveying the wind at different pressures to the sound boards of the various organs in connection with the musical speech of the several groups of pipes. Thus the wind supplied to the solo organ, swell reeds, and large pedal reeds, is the heaviest pressure employed in the instrument for producing the musical intonation of the pipes, namely, 6 inches. The wind pressure to the sound-boards of the great organ and swell flue work is 4 inches, that of the choir organ 2 inches, and the pressure of wind is again reduced in connection with the sound-boards of the echo organ to half an inch, the lightest wind upon which any organ has ever yet been attempted to be voiced. This question of wind pressure as affecting the voicing and musical intonation of the pipes of an organ is one of great importance, and upon the skilful adjustment to the size, diameter, and materials of which the pipes are constructed, depends the sweetness and quality of the musical tones produced. In the organ under notice the very light pressure of wind adopted affords an example for careful study and examination First, for the mellow sweetness and beauty of tone produced; secondly, for the promptness of speech obtained, as rapid as the articulation of a pianoforte string; and thirdly, for the immense volume of sound and power that can be produced from these light pressures, the combined effect of the full organ rivalling almost the artillery of heaven as thunder crash after crash bursts upon the ear. Much of the harsh unmusical tone of modern organs arises from this desire to obtain power at the expense of music by the employment of an over-pressure of wind. That age is not requisite to mellow an organ is demonstrated by listening to the diapasons and foundation stops of the Primrose Hill organ, which have all that ripe and fascinating sweetness of tone characteristic of Silbermann's finest instruments. These light pressures of wind constitute a remarkable feature in the construction of so large an organ. The second series of air trunks which permeate the interior of the instrument are in connection with two large vacuum exhaust bellows which, being continually actuated by the steam-engine used for blowing, maintain a constant vacuum pressure throughout the entire system of trunks, so that at any part of the organ an available mechanical power (that of the pressure of the atmosphere 15 lbs. to the square inch of surface) is at hand to be employed for the multitude of purposes required in a large instrument. To be obliged to have recourse to the old system of wooden rods, trackers, levers, and squares in endless complications, would have so weighted and impeded the action of the organ as greatly to destroy its musical capabilities. In most of the large organs constructed both at home and abroad, many parts of the mechanism are far from being so perfect as to leave no room for anything further to be desired, and the executant upon the instrument rarely is able to portray as rapidly his musical creations mechanically at his finger-ends as those creations in tone-colour flash through his mind. By the introduction of atmospheric vacuum pressure as the "motor" power, there is no complication of mechanical parts; an almost endless system of tubes being carried from the key-board registers to the sound-board sliders of the several organs. These tubes are in connection with powerful exhaust bellows and vacuum power-bellows attached to the sliders, so that any required stop is brought on or off instantaneously, however distant from the key-board. These tubes may be bent and twisted round corners in any direction, and the parts of the organ most difficult of access easily reached. No mechanical force is therefore necessary to be exerted at the keyboards, the mere touch of a key, register, pedal, or finger-button, at once brings its special tube and exhaust arrangement into operation. The wonderful completeness of this system of vacuum-tube action is beautifully illustrated by means of the echo organ—a complete instrument of 16 feet tone, situated some 100 feet from the key-boards of the great organ—and supported on corbels against an opposite wall at an elevation of some 30



View of "The Great Organ" recently erected at the Hall, Primrose Hill, London.

feet from the floor. The action of this organ is electrical, that is, there is no mechanical communication between the performer at the key-board 100 feet distant and the organ pallets which admit the wind to the pipes, save a small rope of 61 insulated copper wires—one wire for each note of the five octaves. The various stops of this distant organ are likewise controlled without mechanism—a series of vacuum tubes alone extending from the registers at the great organ to the sliders of the echo organ—which are thus brought on or off at the will of the performer by a silent action—at once accurate and instantaneous in its manipulation. The effect of this echo organ, is that of a large organ heard at a great distance. Without the aid of the electric action, and vacuum pressure, such an organ could not have been designed. Mechanical action would never have successfully developed such effects at such an extended distance.

The same vacuum system is also applied to the various pneumatic lever arrangements interposed between the keys at the consol and the wind-valves at the sound-boards to relieve the performer from any undue mechanical pressure that might detract from the promptness of repetition and delicacy of touch of the key action, the keyboards being thus rendered as light as that of a grand pianoforte. Such results cannot be obtained so efficiently by the employment of compressed air for a pneumatic power action; compressed air will always prove to be more or less sluggish, a "creeping on" and "creeping off" movement being the result, besides a limit to the aggregate of the instantaneous power that is at command.

The pneumatic drawstop action of the St. George's Hall organ, Liverpool, is a fair illustration of the defects of the compressed air system. In the Primrose Hill organ upwards of forty registers can be simultaneously drawn on or shut off as easily and with the same precision as though only a single stop were drawn. The consol or keyboards of this organ, as will be seen by the engraving, are reversed, that is, the performer faces the audience, the organ being behind, and the echo organ opposite him. The lowest keyboard manual is the "great organ;" the next, or second from the bottom, the "choir organ;" the third in the series the "swell organ;" and the fourth, or upper row of keys, the "solo organ." By a simple mechanical arrangement this fourth keyboard is also used for the electric "echo organ," and also for the carillon, or "bell" organ, otherwise it would have been necessary to have introduced a fifth set of keys, an arrangement at all times objectionable from the increased complications imposed upon the performer. The touch of the carillon organ on the fourth row of keys is expressive like that of the pianoforte key, and gradations of tone and distance are therefore capable of being expressed upon the bells.

In this organ the French ventil system of shutting off or bringing on the wind to a complete family or group of stops by the depression of a pedal has not been adopted, such a system being found inadequate to effect rapidly the almost endless combinations that such a large instrument has at command, the pneumatic combination foot pedals and finger buttons at the keyboards being introduced as a more convenient form of manipulating the registers.

The wind supply of this gigantic organ is furnished from four large reservoirs in the basement, which again supply seventeen reservoirs in connection with the various sound-boards of the organ; the vertical feeders for producing the wind to these reservoirs, as well as for creating the vacuum pressure, are set in motion by an eleven horse-power steam-engine. The wind supply is so ample, that with the power of the full organ it is impossible to exhaust or create unsteadiness in the wind; few organs are properly constructed in this important respect. [illegible] automatic lever engine for regulating the motion and the supply of wind from the vertical feeders into the reservoirs according to the demand of the organ, is [illegible] between the steam-engine and the wind reservoirs, so that the regulation of the wind supply is independent of the speed of the engine, which remains constant. This instrument, which occupied three years in its construction, and was opened in January, 1876, has been erected under the personal supervision of Mr. W. T. Best, of Liverpool, by the eminent organ builders Messrs. Bryceson Brothers, and Morten, of London, for Mr. Nath. J. Holmes, and is erected in the large music-room at the Hall, Primrose Hill Road, built expressly to receive it. The instrument, which stands 50 feet high, 30 feet broad, and 30 feet deep, suffered severe injury from the effects of concussion, in common with the building in which it is erected, at the time of the disastrous explosion of gunpowder on the Regent's Park Canal, near Primrose Hill.

PALÆONTOLOGY AND THE DOCTRINE OF DESCENT

"THE great biological question of the day is the problem of evolution; but geologists, as Kant says, are the archæologists of nature, and the sole direct and irrefragable evidence of the method whereby living things have become what they are is to be sought among fossil remains." Such were the words spoken by Prof. Huxley on a recent occasion, when receiving from the hands of the president of the Geological Society the Wollaston medal; and the assembled geologists, calling to mind his masterly review of the whole question in his address to them in 1870, rejoiced to hear their former president expressing the hope that much of his future labour would be concentrated on this all-important palæontological problem.

The discoveries of such abundant mammalian remains in the Tertiary deposits of the Western territories of America have added much valuable material to that already obtained from the Paris basin, the Sivalik Hills, Pikermi, and many other districts; and we may look forward with confidence to the labours of vertebrate palæontologists for bringing to light many interesting relations between the members of the existing fauna and their ancestral representatives in the later geological periods.

In the meanwhile it may not be uninteresting to point out that among the invertebrata similar evidences of the transitions between life-forms which at first sight appear to constitute perfectly distinct groups, are constantly being detected by palæontologists. No opportunity for doing this more effectively could possibly be desired than that which is afforded by the publication of a most suggestive and valuable monograph by the distinguished palæontologist of Vienna, Dr. Neumayr, in conjunction with M. Paul of the Austrian Geological Survey, a work which has just apppeared in the seventh volume of the *Abhandlungen der k. k. geologischen Reichsanstalt*. The title of this memoir is "Die Congerien- und Paludinen-schichten Slavoniens und deren Faunen; ein Beitrag zur Descendenz-Theorie;" and its authors have earned the thanks alike of geologists and biologists, for the important evidence on the great question of evolution which has been the fruit of their patient researches.

The geological formation which has afforded the evidence in question is the grand series of lacustrine beds, forming the highest portion of the magnificently developed Tertiaries of Eastern Europe, and which constitute the approximate equivalent, in all probability, of our Pliocene; and it is a district on the southern limits of the Austrian Empire, the border-land of that area to which the attention of all Europe has been so painfully drawn for many months past, that has furnished the valuable sections of this formation and the abundant fossil remains, the

discussion of which is the object of the memoir we are noticing. On the northern bank of the Save there rises from the "diluvium" of the vast Hungarian plains an "island" composed of various crystalline, Triassic, and Tertiary rocks, and on the southern side of this tract of older deposits and upheaved along its flanks, between the towns of Alt Gradiska and Turkish Brod, stretches a vast mass of strata, constituting probably the most magnificent representative of the latest stage of the Tertiary period which geologists have as yet had the good fortune to discover.

The strata in question consist of sands and clays, with numerous beds of lignite, and it is to the value of the latter as fuel that we are indebted for those excavations which have afforded such excellent opportunities for studying the successive series of faunas of the formation. The whole of the beds appear to be of lacustrine origin, and have been accumulated, doubtless through the long-continued subsidence of the area, to the enormous thickness of about 2,000 feet; the lower division of the strata known as the "Congerien-Schichten," appears to have been formed under brackish-water conditions, but their upper and by far their thickest portion was certainly accumulated in fresh water. This upper fresh-water series, the "Paludinen-Schichten," is divided by our authors into three principal groups, comprising eight zones, each of which exhibits a well-marked and characteristic fauna.

The group of shells which affords the most interesting evidence of the origin of new forms through descent with modification is that of the genus *Vivipara* or *Paludina*, which occurs in prodigious abundance throughout the whole series of fresh water strata. We shall not, of course, attempt in this place to enter into any details concerning the forty distinct *forms* of this genus (Dr. Neumayr very properly hesitates to call them all *species*) which are named and described in this monograph, and between which, as the authors show, so many connecting links, clearly illustrating the mode of derivation of the newer from the older types, have been detected. On the minds of those who carefully examine the admirably engraved figures given in the plates accompanying this valuable memoir, or still better the very large series of specimens from among which the subjects of these figures are selected, and which are now in the museum of the Reichsanstalt of Vienna, but little doubt will, we suspect, remain that the authors have fully made out their case, and have demonstrated that, beyond all controversy, the species with highly complicated ornamentation were variously derived by descent—the lines of which are in most cases perfectly clear and obvious—from the simple and unornamented *Vivipara achatinoides* of the Congerien-Schichten. It is interesting to notice that a large portion of these unquestionably derived forms depart so widely from the type of the genus *Vivipara* that they have been separated on so high an authority as that of Sandberger, as a new genus, under the name of *Tulotoma*. And hence we are led to the conclusion that a vast number of forms, certainly exhibiting specific distinctions, and, according to some naturalists, differences even entitled to be regarded of generic value, have all a common ancestry.

The vast Tertiary lake-basins of Eastern Europe, in which similar conditions were maintained during such an enormous period, and in which such an unbroken sequence of deposits was accumulated, offer, of course, a particularly favourable opportunity for investigating the relations existing between successive life forms. The disturbing elements, arising from rapid variations in physical conditions attended with the circumstance of the immigration of forms from other areas, and the consequent retreat of the older fauna, the evidence of which is so constantly detected in the case of geological formations of marine origin, are here to a very great extent eliminated; and hence we are able to trace with marvellous precision the exact pedigree of an immense number of diverse forms.

We may, however, be permitted to add that much of the failure in recognising the undoubted ancestral relationships which exist between many marine invertebrate fossil forms, appears to arise either from prejudice on the part of the observers, or from that unfortunate divorce between the work of the physical geologist and the palæontologist, which, in this country at least, tends to confine the former entirely to the field, and the latter as absolutely to the museum. In no way can the admirable results which may be expected to ensue from the combined study of the physical and palæontological characteristics of a formation be better exemplified than by an appeal to the publications of the Geological Reichsanstalt of Vienna. In the same volume of the *Abhandlungen*, which contains the valuable memoir to which we have alluded in the former part of this article, is published a second instalment of Dr. E. Mojsisovics' splendid monograph, "Die Mollusken-Faunen der Zlambach und Hallstätter-Schichten," in which the wonderfully-varied molluscan forms of the Alpine Trias are so admirably described, their derivation traced, and their relations to the Palæozoic and Mesozoic types clearly indicated. While the study of such exceptionally well-preserved faunas as those we have alluded to cannot but impress us with that incompleteness which is undoubtedly the usual characteristic of "the geological record," it nevertheless leads us to entertain the hope, and even to express the certainty, that in the hands of the palæontologist lies the key to that mystery which at present envelopes the laws that have governed the appearance of the successive forms of life.

J. W. JUDD

PRIZES OFFERED BY THE DUTCH SOCIETY OF SCIENCES

THE following subjects for prizes have been proposed by the Dutch Society of Sciences, Haarlem.

1. To make a complete experimental study of the question whether a Daniell element can decompose water, and to submit to a critical examination the theories according to which it does or does not possess this power.

2. What are the meteorological and magnetic phenomena which there are sufficient reasons for believing to be connected with sun-spots?

3 It seems to result from certain experiments of M. Bunsen (*Ann. der Chem. und Pharm.* lxxxv. p. 137, *et. seq.*, 1863), that when mixtures of hydrogen and carbonic oxide are inflamed in a eudiometer with a quantity of oxygen insufficient for complete combustion, there always remains a part of the two combustible gases, and that the quantities of water and of carbonic dioxide which are formed have the relation to each other of simple multiples of their molecular weights. The same will hold good for the quantities of carbonic monoxide and carbonic dioxide which are generated by the combustion of cyanogen by means of a limited quantity of oxygen. The Society requires that these experiments be repeated on a more extended scale, with gaseous mixtures of very diverse composition, and by varying considerably the proportions of the constituents.

4. The researches of Mr. Lockyer concerning the difference of the spectral lines which calcium gives by means of electricity at different temperatures, have excited in a high degree the interest of the Society which requires that these important researches be extended to other elements.

5. Give a critical *résumé* of the observations and experiments concerning the existence of Bacteria in the contagious diseases of man, followed by original researches on the same question, studied in one or more of these diseases.

6, The society requires a simple instrument by which temperatures above 350° C. may be measured in degrees of the air-thermometer.

7. Make researches on the influence which the different colours of the spectrum exercise on the life of the lower animals.

OUR ASTRONOMICAL COLUMN

DE VICO'S COMET OF SHORT PERIOD.—According to the limits for the value of the mean diurnal motion of this comet when it was last observed, in 1844, assigned by Prof. Brünnow from his later researches, the results of which are published in the *Astronomical Notices* issued during his direction of the Observatory of Ann Arbor, Michigan, it would appear that in the absence of any great perturbation a perihelion passage may be expected to occur some time in the twelve months following the beginning of December next, and those who occupy themselves in searching for comets might advantageously institute during that interval a systematic examination of the parts of the sky in which the comet must be situate according to different suppositions as to the date of arrival at perihelion.

The comet of De Vico is most favourably placed for observation when the perihelion falls about Sept. 4, in which case it approaches the earth within 0·2 of our mean distance from the sun. It follows therefore that in 1844, when the comet was in perihelion about midnight on Sept. 2, the conditions were nearly at their best. The comet was detected at Rome on August 22, and was observed by O. Struve at Pulkowa, till Dec. 31. In a masterly discussion by Prof. Brunnow, entitled *Mémoire sur la Comète Elliptique de De Vico*, which gained the prize offered by the Royal Institute of the Netherlands, the elements for 1844 are determined by the most refined methods, and are accurately perturbed not only to the next return in 1850, when from the position of the comet in the heavens there appeared no possibility of its being observed, but to the second return in 1855, when the perihelion is fixed to August 6, ephemerides to facilitate its re-discovery being added to the memoir. From whatever cause, however, the comet was not found in 1855.

The mean motion finally adopted in Brunnow's memoir for the perihelion passage in 1844 corresponds to a revolution of 1996·3 days. In the subsequent calculations to which reference is made in the Ann Arbor *Notices*, he finds a value which diminishes the period of revolution to 1994·0 days, and, as regards the probable error of this determination of the amount of daily sidereal motion (649″·936), he shows that his work rather tends to exclude a greater one than 2″. Nevertheless he particularly insists that too much stress should not be placed on this indication, pointing out the possible influence of a small but variable error in the sun's places, which were taken from Carlini's Tables, and likewise the effect of variation in the form of the comet during the time it was under observation, upon the deduced positions. It does not appear upon what authority Brunnow assumes the reality of material changes in the aspect of the comet. The writer of these lines had the comet under frequent observations particularly after the middle of October, when, as it was receding from the earth, variation of figure by influencing the judgment as to the point to be observed would have had most effect, and well remembers that even to the last week in December, when it had become little more than a glimpse-object with 7 inches aperture, there was still an extremely minute nuclear point, which, with a larger instrument, would admit of very accurate bisection. The comparison with the Pulkowa observations (*Mémoire*, p. 29) affords no evidence of any effect of the kind suggested by Brunnow.

Now there is one point, hitherto it is believed unnoticed in the astronomical periodicals, which bears upon the non-recovery of the comet of late years. Brünnow drew attention to the close approximation of the orbit of De Vico's comet to the orbit of the planet Mars at two points falling near 42° and 287° of heliocentric longitude. If we adopt his later elements, we find that at the first point the distance between the two orbits was 0·0226, and at the latter point 0·0104, distances which, as Brunnow remarks, are "assez petites, pour produire des perturbations sensibles, quelque petite que soit d'ailleurs la masse de la planète perturbatrice;" and it is to be borne in mind that the above distances, small as they are, may have been diminished very sensibly by the effect of accumulated perturbation since 1855, beyond which we have no calculation of the effects of planetary attraction. If the mean diurnal motion in 1855 were as large as 652″·05, a value considerably within Brunnow's suggested limits, the comet might have come into extremely close proximity to Mars at the end of August, 1866, in about 42°·3 heliocentric longitude.

While, however, the above appears a certainly possible contingency, it is not, perhaps, necessary to suppose the existence of any unusual cause for the non recovery of the comet. As occurs with most of these bodies, there are certain periods of the year at which observation would be impracticable; in the case of the comet of De Vico, this disadvantageous period would fall chiefly in the first four months of the year, the perihelion point then falling on the opposite side of the sun to the earth, and the inclination of orbit being very small. How far this may bear upon the question may be judged from the fact of there being no record of this comet having been observed between the year 1678, when Le Verrier identifies it with the comet discovered by Lahire at Paris, and the re-appearance in 1844; and it is worthy of remark that the perihelion passage in 1678 fell only one week earlier than the date which may be considered the most favourable.

A more particular examination of the comet's track in the heavens at different periods of the year is deferred for a future column.

MIRA CETI.—The minimum for 1876, calculated by Argelander's formula of sines from the epoch of Schonfeld's last catalogue, *i.e.*, by applying the same perturbations to minimum as to maximum, falls September 1·2, and may therefore be observed under favourable circumstances. There are comparatively few good determinations of the minima epochs, or of the magnitude of the star at these times, which will justify a hint that it should be watched on this occasion.

RESOURCES OF SERVIA AND BOSNIA

THE small extent of country upon which the eyes of Europe are now centred lies too far out of the beaten tracks of travellers for much to be generally known as to its capabilities or natural resources; nevertheless the country is described in the few existing works as being very fertile, and the soil might be made much more productive were it not for the idle and dirty habits of the people. In these days of "Special Correspondents," the breaking out of a war, even in the remotest parts of the world, is a signal for the dispatch of men of observation, whose duty it is to chronicle the movements of the opposing parties, and, in some cases—we wish it were more often so—to give us glimpses into the habits of the people and the natural features of the country. Thus, we may in the course of a few weeks learn from the public press more about these matters in connection with the small districts now at war with Turkey than we are able to gain from books. The mines of Servia and the forests of Bosnia are two of the principal sources of revenue to the countries. Both iron and copper can be obtained, not only in large quantities, but also of excellent quality. The best Bosnian iron resembles that of Sweden, and is largely used in the manufactories of Gratz, in Styria; quantities also pass into Dalmatia and Servia. These mines are mostly worked by English companies under concessions from the authorities. In the forests are several species of oak, including the evergreen, or Holm Oak (*Quercus Ilex*), the Turkey Oak (*Q. Cerris*), *Q. Ægilops*, *Q. infectoria*, and others. The

first two are of little or no use economically, except perhaps, for their woods, and these are not so highly valued as those of other species; the *Q. Ægilops*, however, which produces large acorns seated in very large cups, is valuable for the sake of these cups, which contain a large quantity of tannin, and are extensively used by tanners and dyers, being imported to a considerable extent from the Levant under the name of Valonia. *Q. infectoria* is also a valuable species, producing, most abundantly, the large shining brown galls known as Mecca galls, used for dyeing purposes, in the manufacture of ink, and in the preparation of tannic and gallic acids. The principal value of the oaks in Bosnia seems to be in their timber, the staple use of which is in the manufacture of staves for casks, immense quantities of which are exported. Amongst the pines occurring in the forests are *Pinus Laricio*, *P. maritima*, *P. halepensis*, and others, as well as the Scots Fir, *P. sylvestris*. Besides these are other forest trees of more or less value, so that if the forests were properly worked, they would not fail to prove of great value. At present, however, the right of cutting timber is held chiefly by foreign speculators, and has proved a source of wealth to many Austrians and Frenchmen who have embarked in it.

One of the most valuable products, both of Bosnia and Servia, as at present developed, lies in their plum crops, many of the peasantry depending entirely on these fruits as the means of subsistence through a great part of the year. The plums, after being gathered, are mostly dried in the form of prunes, the secret or art of drying being known only to themselves. The Bosnian plums are considered of a better quality than those either from Servia, Croatia, or Austria. A quantity of spirit is likewise prepared from these fruits. Amongst other vegetable products of the country may be included tobacco, potatoes, flax, hemp, walnuts; and amongst cereals, wheat, maize, barley, oats, rye, millet, &c. Wheat and maize are the principal food plants consumed in the country, some of the other products being exported in comparatively large quantities.

A notice of the resources of Servia, however brief, could not be closed without a reference to the remarkable traffic in pigs, the value of which amounts to nearly one-half of that of the entire exports of the country. In one year 472,700 of these animals were exported from Servia, the bulk of which are fattened at Steinbruch, near Pesth, in Hungary, where more than 500,000 pigs from various parts are fattened yearly. Their value is not on account of their flesh as an article of food, but exclusively for melting down for their fat.

From these notes it will be seen that in Servia and Bosnia are numerous undeveloped natural resources, and, under a different system than that which now prevails, both forests and mines might be made much more productive.

J. R. J.

NOTES

The French Association for the Advancement of Science will meet this year at Clermont-Ferrand. This meeting will possess unusual interest, as the Puy-de-Dôme Observatory will be opened for inspection for the first time to visitors. That establishment is now in operation, and the results of observations taken are regularly registered in the *Bulletin de l'Observatoire*. A large subvention has been voted by the Municipal Council of Clermont and by the Puy-de-Dôme department, a local Committee has been appointed for the reception of visitors, and the arrangement of excursions to the surrounding mountains, Mont Dore, and others. The session will be presided over by M. Dumas.

The Council of the Yorkshire College of Science have added another subject to those taught at the College, by providing for a chair of Civil and Mechanical Engineering. They have elected as Professor, Mr. George Frederick Armstrong, M.A., F.G.S., Asso. Inst. C.E., who has for the past five years occupied the chair of Civil Engineering and Applied Mechanics in the McGill University, Montreal.

The French Minister of Public Instruction, *L'Explorateur* informs us, is occupied with the organisation of scientific missions having for their object the study of certain determinate points in philology, geography, history, and commerce, both in France and the rest of Europe, as well as in Africa and America. The number of these missions will be thirty-two; twenty-eight are already completely organised. Nine missions will be occupied with natural history; one of these will investigate specially the fauna and flora of Switzerland; four will undertake researches connected with medicine and hygiene, four others dealing with languages; twelve will be occupied with the history and special investigations relative to peoples which have disappeared, or nearly so, as well as to their remaining monuments. Finally, three missions will undertake astronomical and meteorological investigations.

The following are the numbers of visitors to the Loan Collection of Scientific Apparatus during the week ending July 22:—Monday, 2,275; Tuesday, 2,466; Wednesday, 486; Thursday, 393; Friday, 441; Saturday, 2,770; total, 8,831. During the present week 12 demonstrations were given on Monday, 12 on Tuesday, 5 on Wednesday; 7 are to be given to-day, 5 to-morrow; and 4 on Saturday, including the daily lectures to science teachers.

M. Schutzenberger has been appointed to succeed the late M. Balard in the Chair of Chemistry in the Collége de France.

An International Congress of Geography will be held at Brussels on Sept. 11. All the governments have been invited by the King of the Belgians to send delegates. The object of this Congress is the organisation of an international scientific expedition to Central Africa.

The "Report of the Radcliffe Observer" for the year ending June 30 last, shows that the work of the Observatory has been carried on with efficiency. In all departments much good work has been done, and it is satisfactory to notice that the "Third Radcliffe Catalogue" has been commenced at last. Mr. Main's observations confirm those of other observers with regard to the recent remarkable absence of spots from the sun.

A letter in the current number of the *Planters' Gazette* draws attention to the continued importation and sale of filth, under the name of tea, which trade is carried on under the eyes, so to speak, of the Government officials themselves. The writers say:—"We have recently seen samples of mouldy refuse and dust which is now being retailed at the east-end at the rate of 2 oz. for 1*d*., or equal to 8*d*. per pound, duty paid. We submitted the samples to an official occupying a responsible position in the city, but were informed that the Government could not interfere, as the rubbish had passed the Custom House. Three or four hundred packages of 'Maloo mixture' have been delivered from one of the up-town warehouses during the fortnight for shipment, we understand, to Rotterdam."

In connection with the recent *Thunderer* disaster, we would draw attention to a lecture given to the Engineering Class in the University of Glasgow by Prof. James Thomson, "On the Principles of estimating Safety and Danger in Structures in respect to their Sufficiency in Strength." It is published by Maclehose of Glasgow.

A French barrister who died recently left by his will two large houses to the city of Paris, for the purpose of establishing a new municipal college. The houses have been sold for the sum

of 1,600,000 francs, and the municipal council is now busy carrying out the conditions of the will. It is said many improvements will be carried out in the new establishment.

A STATUE has been erected at Bayeux (Calvados) to M. de Caumont, who originated forty-two years ago the Congress of the French learned societies of the provinces. This year the meeting will take place at Autun (Haute-Marne) in the beginning of September.

LIEUT. CHRISTIE, R.E., writing to us from Madras with regard to the use of selenium in telegraphy, says that if we could do away with the man (or woman) signaller, and substitute a commutator actuated by a current of electricity generated by the action of light upon a piece of selenium, we should (supposing the sensitiveness of the selenium to be adequate) have a combination capable of enormously increased rapidity. The message to be transmitted would be first set up (by mechanical means) in the Morse character, in long and short *slits* in an opaque screen; and this perforated screen being passed rapidly between the selenium and a source of light, the currents of electricity would be generated which are required for actuating the commutator. The possibility of such a combination depends on the sensitiveness of selenium to the influence of light. Assuming the combination to be possible, the rapidity of signalling would seem to be limited only by either the mechanical conditions of the commutator (or relay), or the power of the printing instrument at the receiving station,

EVERYONE will be glad to hear of Mr. Stanley's safety, and of the success of the African Expedition, of which he is head. From the brief notice in yesterday's *Telegraph*, we learn that several despatches have been received from Mr. Stanley, the last dated April 24, 1876, from Ubagwe, in Unyamwezi, within fifteen days of Ujiji. Mr. Stanley further explored the Victoria Nyanza, and inflicted one of his regrettable "severe punishments" upon the people of Bambireh, for a former attack. The district between Victoria and Abert Lakes was explored, and a "strange tribe of pale-faced people" was met with in the "cold uplands" of a remarkable mountain, Gambaragara. He returned to Uganda, whence he set out to Ujiji, exploring the Kagera River, Speke's "Lake Windermere," and the hot springs of Karagwe. We regret to notice from a *Daily News* telegram that the Italian African Expedition has been badly treated by the "Emir of Zeila."

THE number of denizens of the Southport Aquarium has been lately increased by the birth of no less than 1,000 sea-horses in one of the tanks.

IN Prof. Loomis's "Contributions to Meteorology," fifth paper, just published in the *American Journal of Science and Arts*, an important point suggested is that when barometers are low and temperatures high in Iceland, barometers are high and temperatures low in Central Europe, and similarly that a like relation exists between the barometers and temperatures of the Aleutian Islands and those of the United States—the influence in both cases being most decided during the cold months of the year. The idea here thrown out is deserving of a thorough investigation by the facts of observation owing to its important bearings on weather-forecasting. It is shown in the same paper that, in the course of storms, the amount of rainfall is least when the pressure at the centre of the storm is increasing, or when the storm is diminishing in intensity; and the amount of rainfall is greatest when the pressure at the centre of the storm is decreasing, or when the storm is increasing in intensity, the effect being also most decided during the colder months of the year.

THE French Alpine Club will hold a General Congress at Annecy on August 13, 14, and 15. All the sections of the French Alpine Club will be present, and the English, Italian, and Swiss Alpine Clubs are expected to send a large number of representatives.

THE Vienna earthquake, to which we referred last week, occurred on July 17 at 1.22 P.M. The principal seat of the commotion was Scheibbs, a small country place forty miles west of Vienna; almost every house in Scheibbs has been damaged. The area of the commotion was very large, equal to about two-thirds of England. It reached Austria proper, Moravia, part of Bohemia, and Hungary. The last earthquake in Vienna was on January 3, 1873. Fifteen instances of earthquake have been recorded in Vienna from the beginning of the thirteenth to the end of the eighteenth century. None of them produced any real damage, except those of September, 1590, and December 4, 1689.

THAT International Exhibitions have not quite failed to attract the attention of the world, is proved by the success which is attending the great undertaking at Philadelphia. A pamphlet of sixteen pages "The Forest Products of Michigan at the Centennial Exposition," by Prof. W. J. Beal, of the State Agricultural College, just received, is one of a shoal of similar essays which always emanate from these great shows, and which are often valuable contributions to the knowledge of the natural resources of the countries upon which they treat. Michigan, as is well known, is the head-quarters of the American timber trade; of this fact we are reminded that two-thirds of the best timber known in the New York, Philadelphia, and Boston markets is obtained from Michigan, besides which a good deal comes to Great Britain and Germany. Of North American building woods much in demand in the country may be mentioned pitch-pine, and the timbers of other species of the genus *Pinus*, while among ornamental woods that of *Acer saccharinum*, the sugar or bird's-eye maple, as well as the black walnut, *Juglans nigra*, are extensively used. With the natural characteristic belief in his own country's greatness the author compares unfavourably not only the forests of Great Britain but also those of every other part of the globe, South America included.

MR. G. E. DOBSON, of the Royal Victoria Hospital, Netley, has just issued a very useful monograph of the Asiatic Chiroptera, founded upon a personal examination of almost all the materials available for the study of the Asiatic members of this group both in India and in Europe. To it is added a catalogue of the specimens of bats contained in the collection of the Indian Museum, Calcutta. The confusion hitherto existing in this difficult group of mammals is very great, and Mr. Dobson has done excellent service in putting them to rights. The catalogue is printed in London by order of the Trustees of the Indian Museum.

THE veteran naturalist, Dr. R. Schomburgk, sends us his Report on the Progress and Condition of the Botanic Garden and Government Plantations at Adelaide, South Australia, for the year 1875. The Garden seems to be in a most flourishing condition, the copious and wide-spread rains of the past year having had a most beneficial influence upon it, as upon the country generally. The Zoological branch of the establishment has received many accessions, and a long list is given of plants added during 1875, to those already in cultivation in the Botanic Garden.

THE American naturalists have lately devoted their attention to "Guadeloupe"—not the West Indian Island commonly known by a similar name, but a small island lying off the coast of Lower California, 220 miles south-west of San Diego. Eleven land birds were found by Dr. Palmer upon Guadeloupe Island, and specimens of them were transmitted to the National Museum at Washington. It is a most noteworthy fact that *every one* of these land birds is distinct from those found on the neighbouring

mainland, although each of them has a continental representative more or less nearly related. Variation in Guadeloupe seems to proceed at a rapid pace.

WE have received the Ninth Annual Report of the Peabody Institute of Baltimore, from which we are glad to see that all departments of the Institute have been doing their work satisfactorily during the past year. We notice, from the librarian's report, that of the books taken out of the library a large proportion belonged to the various sciences.

MESSRS. STANLEY of New York and New Britain (U.S.), have devised a metre diagram, intended to supply a want long felt by all who undertake to study or teach the metric system. The diagram contains a full metre, with its various divisions and sub-divisions clearly indicated, and also an English yard with its sub-divisions, so that the two measures can be at once compared. To these are added explanations of the system, a variety of tables, equivalents, rules, &c., the whole forming an excellent apparatus for the effective teaching of this scientific method of measurement.

THE series of the *Bulletins* of the United States National Museum, prepared at the request of the Smithsonian Institution, and published by the authority of the Secretary of the Interior, already embraces some very interesting and important memoirs relating to the collections in the National Gallery. The first of the series, by Prof. Cope, contains generalisations as to the geographical distribution of reptiles. The second *Bulletin*, prepared by Dr. J. H. Kidder, U.S.N., consists of a history of the birds collected by him during the transit of Venus expedition on Kerguelen Island. This, besides describing new species, gives a great deal of information as to the habits of the gulls, petrels, penguins, &c., of that little-known region. The third *Bulletin* completes the notices of the natural history of Kerguelen Island by an article describing the eggs of the birds, together with a list of the plants, rocks, mammals, fishes, molluscs, and other representatives of the peculiar animal life of the South Seas. In the pamphlet is also an enumeration of the specimens collected by Dr. Kershner, of the navy, in New Zealand. The pamphlet concludes with a critical investigation, by Dr. Kidder and Dr. Coues, of *Chionis minor*, the lesser sheath-bill.

THE third edition of Prof. Snow's catalogue of the birds of Kansas has lately been published by the Kansas Academy of Science, and contains some important additions to the previous list. The present enumeration amounts to 294 species, making an addition of twenty-three species and one variety since the publication of the second edition in October, 1872. The number of species mentioned as breeding in the State is 136.

PROF. MARSH continues to find objects of interest in the immense collection of fossil vertebrates gathered by himself and his assistants in the West during the past ten years. We have already referred to his discovery of a new form of pterodactyl, characterised by the entire absence of teeth, and their probable replacement by a horny sheath like that of the bill of modern birds. He now announces two additional fossil birds possessing teeth implanted in sockets. One is a new species of the first division, *Hesperornis*, and the other forms the type of a new genus, *Lestornis* (*L. crassipes*), the remains of which indicated a large swimming bird, fully six feet in length from the bill to the end of the toes.

THE Catholic Universities seem to have been a failure in France. According to an official account published by Government, about a hundred pupils have been registered in law. The number of medical students is limited to a few dozen in medicine, and there are only eight in science. However, the Catholics are collecting funds with unabated spirit, and 3,000,000 francs are said to be in hand for opening a Law Academy at Marseilles.

FROM the Report of the Auckland Institute (New Zealand) for 1875-76, we are glad to see that that society will soon have a new Museum building of its own. The Report contains a list of important papers which have been read at the Institute during the session. From New Zealand also comes the Report of the Auckland Acclimatisation Society, which, amid many discouragements, is doing good work by the introduction of salmon, trout, and various birds into the country.

THE Report of the Rugby School Natural History Society is the largest yet issued, and contains several papers highly creditable to the young members, and showing that their writers are in a fair way of training themselves to be good observers. Among other papers worthy of mention, are the following:— "On the Symmetry of Flowers and Inflorescence," by V. H. Velej; "On Drops," "On Sound," and "On Impressions," by H. F. Newall; "On the Effects produced by Shadows under Water," by H. N. Hutchinson. Appended are various sectional reports and ten plates illustrating the papers, eight of which are drawn by members of the Society. Altogether the Society is to be congratulated on the Report.

A LIST of papers read before the Priestley Club, Leeds, during its first session, October to June, 1875-76, has been published. Thirty-six papers have been read, all of them on subjects of great scientific importance.

MR. G. H. KINAHAN has published in a separate form his paper on "The Lagoons on the South-east Coast of Ireland," read before the Institution of Civil Engineers.

THE *Proceedings* of the Liverpool Naturalists' Field Club, for 1875-6, shows that that Society continues to do good and steady work. There is an interesting address by the President, the Rev. H. H. Higgins, on "The Names of Plants."

PART 4 of Vol. I. of the *Transactions* of the Watford Natural History Society contains a lecture, by Prof. Morris, on "The Physical Structure of the London Basin considered in its relation to the Geology of the neighbourhood of Watford;" a paper by Mr. R. A. Pryor on "The Supposed Chalybeate Spring at Watford, and on the Medicinal Waters in Herts," besides the rainfall in 1875, and miscellaneous notes and observations.

IN reference to Mr. C. G. O'Brien's letter (vol. xiv. p. 123), on the beautiful spring-trap arrangement of the stamens of Kalmia, a correspondent writes that the point has already been noted by Dr. Robert Brown, in his "Manual of Botany," p. 440.

THE following varieties have been added to the tanks of the Royal Westminster Aquarium during the past week:—Toper, or White Hound (*Galeus canis*), Sting Ray (*Trygon pastinaca*), Red Mullet (*Mullus surmulletus*), Boar-fish (*Capros aper*), Comber, or Smooth Serranus (*Serranus cabrilla*), Pope, or Ruff (*Acerina cernua*), Barbel (*Barbus fluviatilis*), English Carp (*Cyprinus carpio*), presented by Mr. W. R. Killick; Sea Cucumbers (*Holothuria niger*).

THE additions to the Zoological Society's Gardens during the past week include eight Jameson's Gulls (*Larus jamesoni*) from Australia, presented by Mr. A. H. Jamrach; a King Vulture (*Gyparchus papa*) from Tropical America, two South American Little Bitterns (*Butorides cyanurus*) from South America, a Green-billed Toucan (*Ramphastos discolorus*), four Sayaca Tanagers (*Tanagra sayaca*), six Festive Tanagers (*Calliste festiva*), six All-green Tanagers (*Chlorophonia viridis*), two Violet Tanagers (*Euphonia violacea*) from Brazil, a Brown Howler (*Mycetes fuscus*) from Panama, a Madagascar Squirrel (*Sciurus madagascarensis*) from Madagascar, purchased; two Australian Bustards (*Eupodotis australis*) from Australia, deposited; an Eland (*Oreas canna*), nine Amherst's Pheasants (*Thaumalea amherstiæ*), thirteen Gold Pheasants (*Thaumalea picta*), bred in the Gardens.

SCIENTIFIC SERIALS

Mind, July.—This number has very little of interest for the general reader. Helmholtz, on the origin and meaning of geometrical axioms, maintains that geometrical axioms, in the form in which it may be maintained that they are not derived from experience, represent no relations of real things, that they have real import only when certain principles of mechanics are conjoined with them, and that then they are amenable to experience, and may be matters of inference.—Prof. Flint makes a clever fight for the non-derivative origin of moral ideas. He is very hard on the associationist philosophers. The laws of association, he says, will not explain how virtue, if at first loved merely as a means to happiness, comes subsequently to be loved for its own sake, apart from happiness. He denies that transformations of this kind are ever performed, and tries to show that in the case of avarice, the typical instance of the associationists, there is no such thing as the love of money for its own sake.—Mr. Pollock attempts to show, in reply to Mr. Sidgwick, that the doctrine of evolution is not quite without ethical value. He doubts whether the problem of the ultimate sanction of ethics in individual thought can strictly be deemed even rational. This is rather sad from our moral philosophers; with theology it has always been rational and simple enough.—Under the title, "The Original Intention of Collective and Abstract Terms," Max Müller endeavours to make out that Mill in his definitions of mind and of matter lost himself among words, and only jumped out of the frying-pan into the fire.—Mr. Shadworth H. Hodgson concludes his papers on philosophy and science. He opposes to pure ontological speculations the psychological impossibility of ever transcending the duality of subject and object. He retains for philosophy, however, a region avowedly beyond science, the same supra-sensible that Lewes rejects.—Mr. Lindsay gives an appreciative account of the Philosophy of Hermann Lotze, whom we are called on to admire as taking account of the spiritual no less than of the mechanical side of the universe. The history of philosophy at Dublin is written by Mr. Monck.—Among the Critical Notices is a reply by Prof. Bain to the arguments by which Mr. Alexander tries, in his "Moral Causation," to establish the doctrine of human freedom. Prof. Bain is exactly in his element, and the argument is exquisitely neat.—In each of the three numbers of *Mind* there have been notes on a question between Mr. Lewes and Prof. Bain, as to the warrant for our belief in the uniformity of nature, which show how difficult it is for philosophers to make themselves understood by one another.
